The spraying process, especially the spray congealing was simulated by cooling the molten samples rapidly at 320°C/min. A DSC thermogram of pure tristearin heated at 10°C/min revealed a single endothermic peak representing the β -form. After rapid cooling of the melt and reheating, an endothermic peak for the α -form and an exothermic peak indicating the recrystallization of the α -form into the β -form, followed by the endothermic peak for the β -form, were detectable. The DSC thermogram of spray-dried tristearin micropellets was similar to the one of the melt-quenched sample. A crystalline modification therefore took place during spray drying because of the rapid solvent removal. The micropellets were then stored at different temperatures to investigate the effect of storage temperature on the polymorphic transitions. Increasing the storage temperature to 37°C resulted in a complete transformation of the unstable polymorphic form into the stable polymorphic form. The melting endotherm of the α -form disappeared. The effect of various emulsifiers such as lecithin or monoglycerides was investigated in order to prevent or delay the transformation of the unstable form into the stable β -form. Adding lecithin to the formulation resulted in a delay of the transformation. The type of glyceride (composition and chain length), solvent, and drugs encapsulated affected the polymorphic transformation, its rate of transformation, and also the surface structure of the microparticles. Spray-congealed lipid micropellets showed a similar thermal behavior as the spray-dried pellets. The smooth surface of the sprayed lipid micropellets was attributed to the unstable polymorphic form. The unstable α -form has various thin and small crystals, resulting in a smooth surface of the crystallized sample. The β - and β' -forms have larger crystals, therefore causing irregular structures of the micropellets. During ageing at elevated temperatures, the lipid micropellets lost their smooth surface structures because of polymorphic transformations.

Novel oral controlled release microspheres using polyglycerolesters of fatty acids and hydrogenated cottonseed oil (HCSO), stearic acid, stearyl alcohol, or glycerol monostearate as carriers were prepared by spray chilling using a rotating disc.^[68] The drug release was related to the hydrophobicity of the wax; the release rate decreased in the following order: stearyl alcohol > stearic acid > glycerol monostearate > carnauba wax > hydrogenated cottonseed oil. Adding

increasing amounts of lactose to HCSO increased the drug release as a result of the leaching of lactose.

A new atomizer operating with ultrasonic energy was used as an alternative to traditional atomizers to prepare wax microparticles by spray congealing.^[69]

Wet Granulation: End-Point Determination and Scale-Up

Michael Levin

Metropolitan Computing Corporation, East Hanover, New Jersey, U.S.A.

INTRODUCTION

Wet granulation is used mainly to improve flow and compressibility of powders, and to prevent segregation of the blend components. Particle size of the granulate is affected by the quantity and feeding rate of the granulating liquid.

Wet massing in a high shear mixing is frequently compared to the fluid bed mixing and to the roller compaction technique,^[1] and the results seem to be formulation dependent. Compared to high shear granulation, low shear or fluid bed process requires less fluid binder, not only resulting in a shorter drying time, but also in a less cohesive material.^[2–4]

For excellent classical review of the wet granulation process, equipment and variables, and measurement instruments available in the field, see papers by Holm et al.^[5–12] These papers have become a standard reference for numerous subsequent publications.

Because of rapid densification and agglomeration that are caused by the shearing and compressing action of the impeller in a high shear single pot system, mixing, granulation, and wet massing can be done relatively quickly and efficiently. The dangers lie in the possibility of overgranulation because of excessive wetting and producing low porosity granules, thus affecting the mechanical properties of the tablets. As the liquid bridges between the particles are formed, granules are subjected to coalescence alongside with some breakage of the bonds.

It stands to reason that mean granule size is strongly dependent on the specific surface area of the excipients, as well as the moisture content and liquid saturation of the agglomerate. During the wet massing stage, granules may increase in size to a certain degree while the intragranular porosity goes down. However, some heating and evaporation may also take place leading to a subsequent decrease in the mean granule size, especially in small-scale mixers.

Load on the main impeller is indicative of granule apparent viscosity and wet mass consistency. It can be seen as an interplay of acceleration (direct impact of the impeller), centrifugal, centripetal, and friction forces that act on the particles.

According to Cliff,^[13,14] binder addition rate controls granule density, while impeller and chopper speed

control the granule size and granulation rate. The end-point controls the mix consistency and reproducibility. Other factors that affect the granule quality include spray position and spray nozzle type, and of course, the product composition. Such variables as mixing time and bowl or product temperature are not independent factors in the process but rather are responses of the primary factors listed above.

WHAT IS AN END-POINT?

End-point can be defined by the formulator as a target particle size mean or distribution. Alternatively, the end-point can be defined in rheological terms. It has been shown^[15] that once you have reached the desired end-point, the granule properties and the subsequent tablet properties are very similar regardless of the granulation processing factors, such as impeller or chopper speed or binder addition rate. I would call this “the principle of equifinality.”

The ultimate goal of any measurement in a granulation process is to estimate the viscosity and density of the granules, and, perhaps, to obtain an indication of the particle size mean and distribution. One of the ways to obtain this information is by measuring the load on the main impeller.

Mixer instrumentation, in general, has numerous benefits. In addition to a possible end-point determination, it can be used to troubleshoot the machine performance (for example, help detect worn-out gears and pulleys or identify mixing and binder irregularities). Instrumentation can serve as a tool for formulation fingerprinting, assure batch reproducibility, aid in raw material evaluation, process optimization, and scale-up.

WHAT CAN BE MEASURED ON A MIXER-GRANULATOR?

Current

Current in direct current (DC) motors can be used as some indication of the load on the main impeller because impeller torque is proportional to current in

some intervals^[13] and therefore, a current meter (ammeter) can be used for small scale DC motors. However, for alternating current motors (most often used in modern mixers), there may be no significant change in the current as motor load varies up to 50% of full scale. At larger loads, the current draw may increase but this increase is not linearly related to load, and, consequently, the current is completely ineffective as a measurement of load. Moreover, the current baseline may shift with time.

Voltage

Voltage measurement generally has no relation to load.

Capacitance

Capacitive sensor responds to the moisture distribution and granule formation.^[16–19] It provided similar end-points (based on the total voltage change) under varying rates of agitation and liquid addition. Capacitive sensor can be threaded into an existing thermocouple port for in-process monitoring.

Conductivity

Conductivity of the damp mass^[20] makes it possible to quantify uniformity of liquid distribution and packing density during wet massing time.

Probe Vibration

Probe vibration analysis^[21,22] requires a specially constructed probe that includes a target plate attached to an accelerometer (for in-process monitoring). This measurement is based on the theory that increasing granule size results in the increase of the acceleration of agglomerates striking the probe target. The method has a potential for granulation monitoring and end-point control.

Boots Diosna Probe

This probe^[23] measured the densification and increase in size of the granules (changes in momentum of granules moving with constant velocity because of a mass change of the granules). The method did not gain popularity because of its invasive nature.

Chopper Speed

Chopper speed has no significant effect on the mean granule size.^[5,6]

Impeller or Motor Shaft Speed

Rate of impeller rotation could be used as some indication of the work being done on the material.^[24] As the motor or impeller power consumption is proportional to the product of torque and speed, the latter is an important factor in evaluating the corresponding load.

Motor Slip and Motor Load Analyzer

Motor slip is the difference between the rotational speed of an idle motor and the motor under load.^[25,26] Motor slip measurements, although relatively inexpensive, do not offer advantages over the power consumption measurements. The method did not gain popularity, probably because the slip is not linearly related to the load,^[27] despite some claims to the contrary.

Impeller Tip Speed

Impeller tip speed corresponds to the shear rate and has been used as a scale-up parameter in fluid mixing.^[28] For processing of lactose granulations in Gral mixers, however, it was shown by Horsthuis et al.^[29] that the same tip speed did not result in the same end-point [in terms of particle size distribution (PSD)]. These findings were contradicted by other studies with Fielder mixers indicating that for a constant tip speed, successful scale-up is possible when liquid volume is proportional to the batch size and wet massing time is related to the ratio of impeller speeds.^[30]

Relative Swept Volume

Relative swept volume, that is, the volume swept by the impeller (and chopper) per unit time, divided by the mixer volume, has been suggested as a scale-up factor.^[11,12,31] This parameter is related to work done on the material and was studied extensively at various blade angles.^[32] Higher swept volume leads to higher temperature and denser granules. However, it was shown by Horsthuis et al.^[29] that the same relative swept volume did not result in the same end-point (in terms of PSD).

Temperature

Product and jacket temperature are usually measured by thermocouples. These response variables are controlled by a variety of factors, notably, the speed of the main impeller and the rate of the binder addition.

Binder Addition Rate

There are conflicting reports on the preferred method of adding the binder. For example, Holm^[32] does not generally recommend adding dry binder to the mix (as commonly done in order to avoid preparation of a binder solution) because homogeneity of binder distribution cannot be assured. Others recommend just the opposite.^[34–36]

Slow continuous addition of water (in case the water-soluble binder is dry mixed) or a binder solution to the mix is a granulation method of choice.^[5,6,10–12,37–44] The granulating fluid should be added at a slow rate to avoid local overwetting.^[33]

If the binder solution is added continuously, then the method of addition (pneumatic or binary nozzle, atomization by pressure nozzle) should be considered in any end-point determination and scale-up.

An alternative to a continuous binder liquid addition method is to add binder liquid all at once^[29] to assure the ease of processing and reproducibility, reduce processing time, and to avoid wet mass densification that may occur during the liquid addition. This latter phenomenon may obscure the scale-up effect of any parameter under investigation.

Power Consumption

One of the most popular and relatively inexpensive measurements is the power consumption of the main mixer motor. It is measured by a watt transducer or a power cell utilizing Hall effect (a measurable transverse voltage between the two radial sides of a current conductor in a magnetic field, an effect discovered by E.H. Hall in 1879).

Power consumption of the mixer motor for end-point determination and scale-up is widely used (Leuenberger^[43] and subsequent work, Holm^[5] and subsequent work, Landin et al.^[45–48], Faure et al.^[49–53], and many others^[16,33,37–44,54,55]) because the measurement is economical, does not require extensive mixer modifications, and is well correlated with the granule growth.

Power consumption correlates with the mean granule size of a granulation,^[8] although the correlation is not always linear in the entire range. Intragranular porosity also shows some correlation with power consumption.^[56] Normalized work of granulation (power profile integrated over time) can accurately determine end-points and is correlated well with properties of the granulates.^[57]

The main problem with the power consumption measurements is that this variable reflects load on the motor rather than load on the impeller. It relates to the overall mixer performance, depends on the motor efficiency, and can change with time regardless of the load.

Motor power consumption is a product of current, voltage, and the so-called power factor. In the range of interest, motor power consumption is generally proportional to load on the motor and, to some degree, can reflect the load on the impeller (Fig. 1).

However, up to 30% of the power consumption of a motor can be attributed to no-load losses because of windage (by cooling fan and air drag), friction in the bearings, and core losses that comprise hysteresis and eddy current losses in the motor magnetic circuit. Load losses include stator and rotor losses (resistance of materials used in the stator, rotor bars, magnetic steel circuit) and stray load losses such as current losses in the windings.^[58]

Attempts to use a no-load (empty bowl, or dry mix) value as a baseline may be confounded by a possible nonlinearity of friction losses with respect to the load.^[59] As the load increases, so does the current draw of the motor. This results in heat generation that further impacts the power consumption.^[27] A simple test might be to run an empty mixer for several hours and see if there is any shift in the baseline. Also, as the motor efficiency drops with age, the baseline most definitely shifts over time.

Motor power consumption is non-linearly related to the power transmitted to the shaft^[60] and the degree of this non-linearity could only be “guestimated.”

Impeller Torque

In a mixing process, changes in torque on the blades and power consumption of the impeller occur as a result of

Fig. 1 Voltage, current, and power consumption of a typical mixer motor.

change in the cohesive force or the tensile strength of the agglomerates in the moistened powder bed.

Direct torque measurement requires installation of strain gages on the impeller shaft or on the coupling between the motor and impeller shaft (Fig. 2). As the shaft is rotating, a device called slip ring is used to transmit the signal to the stationary data acquisition system.

Planetary mixer instrumentation for direct torque measurement does not substantially differ from that of a high shear mixer. Engineering design should only take into account the planetary motion in addition to shaft rotation.^[61]

Impeller torque is an excellent in-line PAT measurement of the load on the main impeller.^[39,62]

Torque Rheometer

A torque rheometer is a device that provides an off-line measurement of torque required to rotate the blades of the device and this torque can be used to assess rheological properties of the granulation. It has been extensively used for end-point determination.^[45,63–65] The torque values thus obtained were termed as “measure of wet mass consistency.”^[50,51,66]

One of the main concerns is that using the torque value that the unit is reporting instead of the dynamic viscosity for calculation of Reynolds numbers renders the latter to become dimensional. Therefore, the Reynolds number calculated from torque rheometer data is referred to as “pseudo-Reynolds” dimensional number. Because of the fact that torque was shown to be proportional to a kinematic (rather than dynamic)

viscosity,^[67] it can have a conditional use in the dimensional analysis of the process, as will be shown below.

Reaction Torque

By the third law of Newton, for every force there is a counterforce, collinear, equal and opposite in direction. As the impeller shaft rotates, the motor tries to rotate in the opposite direction, but it does not because it is bolted in place. The tensions in the stationary motor base can be measured by a reaction torque transducer.

Reaction torque is a less expensive alternative to direct impeller torque and is recommended for mixers that have the motor and impeller shafts axially aligned (in this case, the reaction torque is equal to direct torque and is opposite in sign).

Other Possibilities

When the agglomeration process is progressing very rapidly, neither power consumption nor torque on the impeller may be sensitive enough to adequately reflect changes in the material. Some investigators feel that other measurements, such as torque or force on the impeller blades may be better suited to monitor such events.

There are other ideas floating around, for example, use of neural network to describe and predict the behavior of the wet granulation^[68] or control the end-point by rapid image processing system.^[69]

A technique for measuring tensile strength of granules, in addition to power consumption measurement, to facilitate optimal end-point determination was recently described by Betz, Bürgin, and Leuenberger.^[54]

Powder flow patterns in wet granulation can be studied using positron emission particle tracking.^[70] Eventually, this and similar techniques can be used to validate various mathematical and statistical models of the process.

Emerging Technology

Acoustic

Applicability of piezoelectric acoustic emission sensors to end-point determination has been studied since the beginning of this century.^[71] The technique is very promising, especially because it is non-invasive, sensitive, and relatively inexpensive. Granulation process signatures obtained with acoustic transducer can be used to monitor changes in particle size, flow, and compression properties.^[72,73]

Fig. 2 Schematic of a direct impeller torque transducer.

Near-infrared

Use of a refractive near-infrared (NIR) moisture sensor for end-point determination of wet granulation was described by several authors.^[74,75] There are technological challenges associated with this approach, as the sensor can only measure the amount of water at the powder surface.

NIR monitoring of the granulation process was attempted by researchers at many major pharmaceutical corporations with a modest success. In particular, yet unpublished work by David Rudd of Glaxo-SmithKline in England should be mentioned as a part of the global effort in the field of Process Analytical Technology.

Focused beam reflectance measurement

Focused beam reflectance measurement (FBRM) is a particle size determination technique based on a laser beam focusing in the vicinity of a sapphire window of a probe. The beam follows a circular path at speeds of up to 6 m/sec. When it intersects with the edge of a particle passing by a window surface, an optical collector records a backscatter signal. The time interval of the signal multiplied by the beam speed represents a chord length between two points on the edge of a particle. The chord length distribution (CLD) can be recalculated to represent either a number or volume weighted PSD.

In many cases, where precision is more important than accuracy, CLD measurements are adequate to monitor dynamic changes in process parameters related to the particle size and shape, concentration, and rheology of fluid suspensions.

Several attempts were made to evaluate the use of FBRM particle size analyzer as a potential tool for granulation end-point determination.^[76] Dilworth et al.^[77] have compared power consumption, FBRM, and acoustic signals in a study of a wet granulation process in Fielder PMA 200 mixer. It was found that these techniques were complimentary, with FBRM probe capable to follow median granule size growth even when the power consumption curve showed a plateau.

A major disadvantage of the FBRM method is that the measured CLD does not directly represent a PSD. Conversion of CLD to PSD is not straightforward and requires sophisticated mathematical software that is not easy to validate. Moreover, CLD depends on optical properties and shape of the particles, as well as the focal point position. The total number of counts measured is a function both of solids concentration and probe location.

END-POINT DETERMINATION

End-point detection in wet granulation has become a major scientific and technological challenge.^[78] Monitoring granulation is most commonly achieved by collecting either power or torque signals, or both. In what follows, we will compare both methods.

Torque vs. Power

When we say, “power consumption,” we usually refer to the main motor. It reflects the load on the motor because of useful work, as well as the power needed to run the motor itself (losses because of eddy currents, friction in couplings, etc.).

It is quite possible (and, indeed, quite pertinent) to talk about the power consumption of the impeller, which is, obviously, quantitatively less than the power consumption of the motor and relates directly to the load on the impeller.

$$\text{Power} \sim \text{Torque} \times \text{Speed}$$

Impeller power consumption can be calculated as a product of the direct torque, rotational impeller speed, and a coefficient (usually equal to 2π times a unit conversion factor, if required).

The power consumption of the mixer motor differs from that of the impeller by the variable amount of power draw imposed by various sources (mixer condition, transmission, gears, couplings, motor condition, etc.).

Compared to impeller torque, motor power consumption is easier to measure; wattmeters are inexpensive and can be installed with almost no downtime. However, motor power signal may not be sensitive enough for specific products or processing conditions. Wear and tear of mixer and motor may cause power fluctuations. Moreover, power baseline may shift with load.

Impeller torque, on the other hand, is closer to where the action is, and is directly related to the load on the impeller. Torque is not affected by mixer condition.

Although the motor power consumption is strongly correlated with the torque on the impeller,^[39] it is less sensitive to high frequency oscillations caused by direct impact of particles on the blades as evidenced by Fast Fourier Transform (FFT) technique.^[16]

Power consumption or torque fluctuations are influenced by granule properties (PSD, shape index, and apparent density) and the granulation time. Fluctuation of torque/power consumption and intensity of spectrum obtained by FFT analysis can be used for end-point determination.^[38]

It was observed that when the end-point region of a granulation is reached, the frequency distribution of a power consumption signal reaches a steady state.^[79] It should be repeated here that torque shows more sensitivity to high frequency oscillations.

Torque and Power Profiles

Fig. 3 illustrates the classical power and torque profiles that start with a dry mixing stage, rise steeply with binder solution addition, level off into a plateau, and then exhibit overgranulation stage. The power and torque signals have similar shape and are strongly correlated. The pattern shows a plateau region where power consumption or torque is relatively stable.

The peak of the derivative indicates the inflection point of the signal. Based on the theory by Leuenberger (1979 and subsequent work), usable granulates can be obtained in the region that starts from the peak of the signal derivative with respect to time and extends well into the plateau area.^[44] Prior to the inflection point, a continuous binder solution addition may require variable quantities of liquid. After that point, the process is well defined and the amount of binder solution required to reach a desired end-point may be more or less constant.

Torque or power consumption pattern of a mixer is a function of the viscosity of both the granulate and binder. With the increasing viscosity, the plateau is shortened and sometimes vanishes completely, thereby increasing the need to stop the mixer at the exact end-point.

At low impeller speeds or high liquid addition rates, the classic S-shape of the power consumption curve may become distorted with a steep rise leading into overgranulation.^[9]

The area under the torque-time curve is related to the energy of mixing and can be used as an end-point parameter. Area under power consumption curve divided by the load gives the specific energy consumed by the granulation process. This quantity is well correlated with the relative swept volume.^[11,12,32]

The consumed energy is completely converted into heat of the wet mass,^[7] so that the temperature rise during mixing shows some correlation with relative swept volume and Froude number^[29] that relates the inertial stress to the gravitational force per unit area acting on the material.

Fig. 4 represents a record of a typical granulation batch done by an experienced operator on large Hobart mixer. You can see that the batch was stopped on the downslope of the derivative.

On a Fig. 5 you can see another batch made by the same operator. This time it is a power consumption trace, but again it extends beyond the peak of the derivative and the end-point thus can be deemed reproducible.

In the batch represented in Fig. 6, a novice operator trainee has stopped the batch well before the peak of the derivative. This required a major adjustment of the tableting operation (force and speed) to produce tablets in an acceptable range of material properties (hardness and friability).

In this batch (Fig. 7), the same novice operator has stopped the granulation process, opened the lid, took a sample, and decided to granulate for another 10 sec. You can see that there is no indication that the peak of the derivative was reached at the end-point.

Thus, it seems that the monitoring torque or power can fingerprint not only the product, but the process and the operators as well.

A number of publications relate to the practical experience of operators on the production floor.^[33,80–82]

Fig. 3 Impeller torque and motor power consumption for a small high shear mixer (Fielder PMA 10).

Fig. 4 A torque profile in a typical production batch.

Fig. 6 A batch by a novice operator (power consumption profile).

End-Point Optimization

Agglomeration of particles in wet granulation have been studied extensively.^[24,83] The optimal end-point can be thought of as the factor affecting a number of agglomerate properties (Fig. 8).

With so many variables involved in a granulation process, it is no wonder that more and more researchers throw in a number of factors together in an attempt to arrive at an optimum response.^[34,84–92]

The final goal of any granulation process is a solid dosage form, such as tablets. Therefore, when optimizing a granulation process, the list of factors affecting tablet properties may include both the granulation

end-point and the tableting processing parameters, such as compression force or tablet press speed.

In one of the most interesting works based on the experimental design approach, an attempt was made to find a statistical relationship between the major factors affecting both granulation and compaction, namely, granulation end-point, press speed (dwell time), and compression force.^[93] The resulting equation allowed optimization of such standard response parameters as tablet hardness, friability, and disintegration time. This study has also investigated the possibility of adjusting the tableting parameters in order to account for an inherent variability of a wet granulation process.

Multivariate optimization of wet granulation may include hardness, disintegration, and ejection as response variables.^[94] Compressibility property of

Fig. 5 Another batch by the same operator (power consumption profile).

Fig. 7 Another batch by inexperienced operator (torque profile).

Fig. 8 Wet granulation end-point as a factor in tableting optimization.

granulations is extremely sensitive to various processing parameters of wet granulation.^[95]

Recently, the experimental design procedure was applied to low shear wet granulation^[96] with a factorial design used to evaluate the influence of such factors as binder strength and agitator speed.

End-Point Reproducibility

As will be shown in the following section, for every blend and a fixed set of values for processing factors (such as mixer geometry, blade speed, powder volume, amount, and method of addition of granulating liquid), a wet granulation process state (end-point) is completely characterized by rheological properties of the wet mass (density, viscosity), which are, in turn, a function of particle size, shape, and other properties. The process can be quantified with the help of dimensionless Newton Power Number N_p that will assume a certain numerical value for every state (condition) of the granulate. Under fixed processing conditions, N_p will be proportional to Net Power Consumption ΔP for any end-point (defined, in part, by wet mass density). Thus, in order to reproduce an end-point, it is sometimes sufficient to monitor power of the impeller (or the motor) and stop when a predefined net level of the signal is reached. If, however, any of the processing variables or the rheological definition of the end-point has changed, a more sophisticated approach is required, as described below.

END-POINT SCALE-UP

Scale-Up Attempts

Numerous studies were undertaken in an attempt to determine empirically (and, lately, with a solid

theoretical foundation) useful scale-up parameters of the wet granulation process.^[50,91,97]

In a seminal and elegant work published in 1993, Horsthuis et al. from Organon in The Netherlands have studied granulation process in Gral mixers of 10, 75, and 300 L size.^[29] Comparing relative swept volume, blade tip speed and Froude numbers with respect to end-point determination (as expressed by the time after which there is no detectable change in particle size), they have concluded that only constant Froude numbers result in a comparable end-point.

In another attempt to determine good scale-up parameters, the University of Maryland group under the direction of Dr. Larry Augsburger^[30] has applied the ideas of Leuenberger and Horsthuis to show that, for a specific material, end-point can be expressed in terms of wet massing time. For a constant ratio of a binder volume to a batch size, this factor was found to be inversely proportional to impeller speed when the impeller tip speed was held constant for all batches. However, this result was not corroborated by other studies or other materials.

Yet another example of semiempirical scale-up effort^[97] was based on the fact that normalized power profiles are very similar and allow for direct comparison of different size granulators, at least for the equipment and materials used in the study. Normalized power curve rose at a relatively constant rate in the region where the ratio of water to dry mass is 0.1–0.2 (“slope plateau”). Despite a rapid increase in the slope of the power curve, the desired end-point was still detectable at a moment when the slope of the power consumption signal exceeded the plateau level by a factor of 5 (empirical observation). Using this approach, an acceptable end-point (target particle size of 135 μm) was first established on a 10-L Fielder and then scaled to 65-L Fielder and 250-L Diosna.

Dimensional Analysis

A rational approach to scale-up using dimensional analysis has been in use in chemical engineering for quite some time. This approach, based on the use of process similarities between different scales, was being applied to pharmaceutical granulation since the early work of Leuenberger in 1979.^[43]

Dimensional analysis is a method for producing dimensionless numbers that completely describe the process. The analysis should be carried out before the measurements are made because dimensionless numbers essentially condense the frame in which the measurements are performed and evaluated. The method can be applied even when the equations governing the process are not known. Dimensional analytical procedure was first proposed by Rayleigh in 1915.^[98]

Principle of Similitude

Imagine that you have successfully scaled up from a 10-L batch to 300-L batch. What exactly happened? You may say: “I got lucky.” Apart from luck, there had to be similarity in the processing and the end-point conditions of the wet mass of the two batches.

According to the modeling theory, two processes may be considered similar if there is a geometrical, kinematic, and dynamic similarity.^[99]

Two systems are called geometrically similar if they have the same ratio of characteristic linear dimensions. For example, two cylindrical mixing vessels are geometrically similar if they have the same ratio of height to diameter.

Two geometrically similar systems are called kinematically similar if they have the same ratio of velocities between the corresponding system points. Two kinematically similar systems are dynamically similar when they have the same ratio of forces between the corresponding points. Dynamic similitude for wet granulation would imply that the wet mass flow patterns in the bowl are similar.

The gist of dimensionless analysis is as follows: For any two dynamically similar systems, all the dimensionless numbers necessary to describe the process have the same numerical value.^[100] Once a process is expressed in terms of dimensionless variables, we are magically transferred to a world where there is no space and no time. Therefore, there is no scale and, consequently, there are no scale-up problems. The process is characterized solely by numerical values of the dimensionless variables (numbers). In other words, dimensionless representation of the process is scale-invariant.

Lack of geometrical similarity often is the main obstacle in applying the dimensional analysis to solving the scale-up problems. It was shown, for example, that Collette Gral 10, 75, and 300 are not geometrically similar.^[29] In such cases, a proper correction to the resulting equations is required.

Dimensionless Numbers

Dimensionless numbers most commonly used to describe the wet granulation process are Newton, Froude, and Reynolds:

$$N_p = \Delta P / (\rho \times n^3 \times d^5) \quad \text{Newton(power)}$$

$$Fr = n^2 \times d / g \quad \text{Froude}$$

$$Re = d^2 \times n \times \rho / \eta \quad \text{Reynolds}$$

(for list of symbols, notation, and dimensions, see Appendix).

Newton (power) number, which relates the drag force acting on a unit area of the impeller and the inertial stress, represents a measure of power requirement to overcome friction in fluid flow in a stirred reactor. In mixer-granulation applications, this number can be calculated from the power consumption of the impeller or estimated from the power consumption of the motor.

Froude Number^[101] has been described for powder blending and was suggested as a criterion for dynamic similarity and a scale-up parameter in wet granulation.^[29] The mechanics of the phenomenon was described as interplay of the centrifugal force (pushing the particles against the mixer wall) and the centripetal force produced by the wall, creating a “compaction zone.”

Reynolds numbers relate the inertial force to the viscous force.^[102] They are frequently used to describe mixing processes and viscous flow, especially in chemical engineering.^[103]

We have seen that there exists a sort of “principle of equifinality” that states: “An end-point is an end-point is and end-point, no matter how it was obtained.” Different processing pathways can lead to different end-points, each with its own set of granulation properties. However, once an end-point is reached, it is characterized by certain numerical values of the dimensionless variables describing the process, and these values will be independent of scale.

At the same end-point, no matter how defined, the rheological and dimensional properties of the granules are similar. As we will see from the examples described below, that means that the density and dynamic viscosity of the wet mass are constant, and the only variables that are left are the process variables, namely batch mass, impeller diameter and speed, and the geometry of the vessel.

Comparison of Attainable Froude Numbers

Horsthuis et al.^[29] showed that an end-point could be reproduced and scaled up in Gral mixers by keeping the Froude numbers constant. For the same end-point, in dynamically similar mixers (same geometrical ratios, and same flow patterns), all dimensionless numbers describing the system should have the same numerical value, but Froude numbers for any mixer are easiest to compute.

Each mixer has a range of attainable Froude numbers, and an end-point transfer between mixers can only be achieved when such ranges overlap. Fig. 9 represents such a range for Collette Gral mixers. It can be seen that Gral 10 and Gral 150 have no overlap of Froude number ranges, and therefore, a direct scale-up is not possible (in addition, Gral mixers are not exactly similar geometrically, as was stated elsewhere).

Fig. 9 The range of Froude numbers for Collette Gral high-shear mixers.

The range of Froude numbers for Fielder PMA series mixers is shown on Fig. 10. The 10-L laboratory scale mixer at its lowest speed settings can reach the Froude numbers of all other mixers, except one. These considerations can be useful for planning a scale-up or technology transfer operation.

Π -theorem (Buckingham)

The so-called Π -theorem (or Buckingham theorem)^[104] states:

Every physical relationship between n dimensional variables and constants $f(x_0, x_1, x_2, \dots, x_n) = 0$ can be reduced to a relationship $f(\Pi_0, \Pi_1, \dots, \Pi_m) = 0$ between $m = n - r$ mutually independent dimensionless groups, where r = number of dimensional units, i.e., fundamental units (rank of the dimensional matrix).

Scientific Scale-Up Procedure

1. Describe the process using a complete set of dimensionless numbers, and

2. Match these numbers at different scales.

The dimensionless space in which the measurements are presented or measured will make the process “scale invariant.”

Relevance List

The dimensional analysis starts with a list of all variables, thought to be important for the process, being analyzed (the so-called “relevance list”).

To set up a relevance list for any process, one needs to compile a complete set of all relevant and mutually independent variables and constants that affect the process. The word “complete” is crucial here. All entries in the list can be subdivided into geometric, physical, and operational. Each relevance list should include only one target (dependent “response”) variable.

Many pitfalls of dimensional analysis are associated with the selection of the reference list, target variable, or measurement errors (e.g., when friction losses are of the same order of magnitude as the power consumption of the motor). The larger the scale-up factor, the more precise the measurements of the smaller scale have to be.^[100]

Dimensional Matrix

Dimensional analysis can be simplified by arranging all relevant variables from the relevance list in a matrix form, with a subsequent transformation yielding the required dimensionless numbers. The dimensional matrix consists of a square core matrix and a residual

Fig. 10 The range of Froude numbers for Fielder PMA high-shear mixers.

Table 1 The relevance list used by Leuenberger (1983)

Quantity	Symbol	Units	Dimensions
Power consumption	P	Watt	$M L^2 T^{-3}$
Specific density	ρ	kg/m^3	$M L^{-3}$
Blade diameter	d	m	L
Blade velocity	n	rev/sec	T^{-1}
Binder amount	s	kg	M
Bowl volume	V_b	m^3	L^3
Gravitational constant	g	m/sec^2	$L T^{-2}$
Bowl height	H	m	L

matrix (you will see examples in the case studies below).

The rows of the matrix consist of the basic dimensions, while the columns represent the physical quantities from the relevance list. The most important physical properties and process-related parameters, as well as the “target” variable (that is, the one we would like to predict on the basis of other variables) are placed in one of the columns of the residual matrix.

The core matrix is then linearly transformed into a matrix of unity where the main diagonal consists only of ones and the remaining elements are all zero. The dimensionless numbers are then created as a ratio of the residual matrix and the core matrix with the exponents indicated in the residual matrix. This rather simple process will be illustrated below in the examples.

Case Study I: Leuenberger (1979,1983)

This example is based on the groundbreaking studies conducted by Leuenberger at the University of Basel and Sandoz AG.^[43,105–108]

The Relevance List in Table 1 reflects certain assumptions used to simplify the model, namely, that there are short-range interactions only and no viscosity factor (and therefore, no Reynolds number).

Why do we have to consider the gravitational constant? Well, imagine the same process to be done on the moon—would you expect any difference?

One target variable (Power consumption) and seven process variables/constants thus represent the number $n = 8$ of the Π -theorem. The number of basic dimensions $r = 3$ (M, L, and T). According to the theorem, the process can be reduced to the relationship between $m = n - r = 8 - 3 = 5$ mutually independent dimensionless groups.

The Dimensional Matrix in Table 2 was constructed as described above, with the rows listing the basic dimensions and the columns indicating the physical quantities from the relevance list.

Transformation of the dimensional matrix (Table 3) into a unity matrix is straightforward. To transform-3 in L-row/ ρ -column into zero, one linear transformation is required. The subsequent multiplication of the T-row by -1 transfers the -1 of the n-column to +1.

The five dimensionless groups are formed from the five columns of the residual matrix by dividing each element of the residual matrix by the column headers of the unity matrix, with the exponents indicated in the residual matrix.

The residual matrix contains five columns; therefore five dimensionless Π groups (numbers) will be formed (Table 4).

The end result of the dimensional analysis is an expression of the form

$$\Pi_0 = f(\Pi_1, \Pi_2, \Pi_3, \Pi_4)$$

Assuming that the groups Π_2, Π_3, Π_4 are “essentially constant,” the Π -space can be reduced to a simple relationship $\Pi_0 = f(\Pi_1)$, that is, the value of Newton number N_p at any point in the process is a function of the specific amount of granulating liquid.

Up to this point, all the considerations were rather theoretical. From the theory of modeling, we know that the above dimensional groups are functionally related. The form of this functional relationship f , however, can be established only through experiments.

Leuenberger and his group have empirically established that the characteristic (that is, relative to the batch size) amount of binder liquid required to reach a desired end-point (as expressed by the absolute value of N_p and, by proxy, in terms of net power

Table 2 The dimensional matrix for case study I

	Core matrix			Residual matrix

consumption ΔP) is “scale-up invariable,” that is, independent of the batch size (Fig. 11), thus specifying the functional dependence f and establishing rational basis for granulation scale-up.

Experiments with five different planetary mixers with batch sizes ranging from 3.75 kg to 60 kg showed that, if the binder is mixed in as a dry powder and then liquid is added at a constant rate proportional to the batch size, the ratio of the granulation liquid quantity to a batch size is constant. This was shown for non-viscous binders.

The ratio of quantity of granulating liquid to batch size at the inflection point of power vs. time curve is constant irrespective of batch size and type of machine. Moreover, for a constant rate of low viscosity binder addition proportional to the batch size, the rate of change (slope or time derivative) of torque or power consumption curve is linearly related to the batch size for a wide spectrum of high shear and planetary mixers. In other words, the process end-point, as determined in a certain region of the curve, is a practically proven scale-up parameter for moving the product from laboratory to production mixers of different sizes and manufacturers.

As we have indicated before, for any desired end-point, the power consumption will be proportional to the Newton power number, at a constant mixer speed.

The Leuenberger’s ideas relating to the use of power consumption for wet granulation end-point determination were tested and implemented by numerous researchers.^[9,33,37,41,43]

In 2001, Holm, Schaefer, and Larsen^[78] have applied the Leuenberger method to study various processing factors and their effect on the correlation between power consumption and granule growth. They have found that such a correlation did indeed exist but was dependent, as expected, on the impeller design, the impeller speed, and the type of binder. The conclusion was that it was possible to control the liquid addition by the level detection method whereby the liquid addition is stopped at a predetermined level of power consumption. An alternative approach involves an inflection point (peak of the signal derivative with respect to time).

Different vessel and blade geometry will contribute to the differences in absolute values of the signals. However, the signal profile of a given granulate composition in a high shear mixer is very similar to the one obtained in a planetary mixer.

For accuracy, in power number N_p calculations, the power of the load on the impeller rather than the mixer motor should be used. Before attempting to use dimensional analysis, one has to measure/estimate power losses for empty bowl or dry stage mixing. Unlike power consumption of the impeller (based on torque measurements), the baseline for motor power consumption does not stay constant and changes significantly with load on the impeller, mixer condition, or motor efficiency. This may present inherent difficulties in using power meters instead of torque. Torque, of course, is directly proportional to power drawn by the impeller (the power number can be determined

Table 4 Dimensionless Π groups^a

Π group	Expression	Definition
Π_0	$P/(\rho^1 \times d^5 \times n^3) = N_p$	Newton (Power) number

from the torque and speed measurements) and has a relatively constant baseline.

Case Study II: Landin et al. (1996)

Scale-up in fixed bowl mixer-granulators has been studied by Rowe and Cliff's group^[46] using the classical dimensionless numbers of Newton (power), Reynolds, and Froude to predict the end-point in geometrically similar high-shear Fielder PMA 25, 100, and 600 L machines.

The relevance list (Table 5) included power consumption of the impeller (as a response) and six factor quantities: impeller diameter, impeller speed, vessel height, specific density and dynamic viscosity of the wet mass, and the gravitational constant.

Note that dynamic viscosity has replaced the binder amount and bowl volume of the Leuenberger's relevance list, thus making it applicable to viscous binders and allowing long-range particle interactions responsible for friction.

The dimensional matrix for Case Study II (Table 6) is different from Table 2: the columns for mass [M] and bowl volume [L³] are replaced by a viscosity

Table 5 Relevance list for case study II (Landin et al., 1996)

Quantity	Symbol	Units	Dimensions
Power consumption	P	Watt	$M L^2 T^{-3}$
Specific density	ρ	kg/m ³	$M L^{-3}$
Blade diameter	d	m	L
Blade speed	n	rev/sec	T^{-1}
Dynamic viscosity	η	Pa sec	$M L^{-1} T^{-1}$
Gravitational constant	g	m/sec ²	$L T^{-2}$
Bowl height	H	m	L

[$M L^{-1} T^{-1}$] column. Evidently, it was assumed that the mass and volume could be adequately represented in the relevance list by the density and powder height in a semicylindrical vessel of a known diameter.

The residual matrix (Table 7) contains four columns; therefore four dimensionless Π groups (numbers) will be formed, in accordance with the Π -theorem (7 variables – 3 dimensions = 4 dimensionless groups).

Table 8 lists the resulting groups; they correspond to Newton power, Reynolds, and Froude numbers, and the ratio of characteristic lengths.

Under the assumed condition of dynamic similarity, from the dimensional analysis theory, it follows that $\Pi_0 = f(\Pi_1, \Pi_2, \Pi_3)$, and, therefore, $N_p = f(\text{Re}, \text{Fr}, H/d)$.

When corrections for gross vortexing, geometric dissimilarities, and powder bed height variation were made, data from all mixers (Fielder PMA 25, 100 and 600 L) correlated to the extent that allows predictions of the optimum end-point conditions. The linear regression of Newton number (power) on the product of adjusted Reynolds number, Froude number, and the Geometric number (in log/log domain) yields (Fig. 12) an equation of the form:

$$\log_{10} N_p = a \log_{10}(\text{Re} \times \text{Fr} \times H/d) + b$$

where $b = 796$ and $a = -0.732$.

Theoretically, in such a representation of the granulation process, a slope $a = -1$ would signify a true laminar flow whereby a slope significantly less than -1 or approaching 0 would indicate turbulence. Thus, one would expect planetary mixers to have a slope closer to -1 compared to that of high shear granulators. However, the results described here and in subsequent studies do not show a clear difference between the slopes of regression for planetary and high-shear mixers.

However, the correlation coefficient of 0.7854 for the final curve fitting effort indicates the presence of many unexplained outlier points. One of the possible concerns was an inherent error in measuring the height of the powder bed from the wet mass density.

In a subsequent communication^[47] it was shown that, in order to maintain geometric similarity, it is important to keep the batch size proportional to the bowl shape.

Another concern is the interpretation of data from mixer torque rheometer that was used to assess the viscosity of wet granulation. The torque values obtained from the rheometer were labeled “wet mass consistency” and were used instead of dynamic viscosity to calculate Reynolds numbers. It was shown^[45,66] that such torque values are proportional to kinematic

Table 6 The dimensional matrix for case study II

	Core matrix			Residual matrix			
	ρ	d	n	P	η	g	H
Mass (M)	1	0	0	1	1	0	0
Length (L)	-3	1	0	2	-1	1	1
Time (T)	0	0	-1	-3	-1	-2	0

viscosity $\nu = \eta/\rho$ rather than dynamic viscosity η required to compute Reynolds numbers. The degree of proportionality between ν and η was found to be formulation dependent.

Consequently, it was prudent to acknowledge that the above regression equation is not dimensionless because for all practical purposes, the Reynolds number Re was replaced by ΨRe , what the authors called a “pseudo Reynolds number” with the dimensions $[\text{L}^{-3}\text{T}]$. This predicament did not deter a plethora of other studies in the same line of reasoning to be published in recent years. Note that this pseudo Reynolds number has a physical meaning: it is a reciprocal of volumetric flow rate.

Case Study III: Faure et al. (1998)

The same approach was applied to planetary Hobart AE240 mixer with two interchangeable bowls, 5 and 8.5 L.^[49] Assuming the absence of chemical reaction and heat transfer, the following relevance list for the wet granulation process was suggested (Table 9):

One difference from Table 5 of the previous study is the use of net power ΔP that was defined as motor power consumption under load minus the dry blending baseline level.

An assumption was made that a motor drive speed is proportional to the impeller blade speed. Another consideration was that the ratio of characteristic lengths h/d is proportional to (and, therefore, can be replaced by) a fill ratio V_m/V_b , which was, in turn, shown to be proportional to (and therefore, could be replaced in the final equation by) the quantity $m/(\rho \times d^3)$. This is a preferred method of representing a fill ratio because the wet mass m is easier to measure than the height of the granulation bed in the bowl.

Dimensional analysis and application of the Buckingham theorem lead to four dimensionless quantities that adequately describe the process: Ne , ΨRe , Fr , and h/d . As before, a relationship of the form

$$N_p = 10^b(\Psi\text{Re} \times \text{Fr} \times \rho R_b^3/m)^a, \text{ or}$$

$$\log_{10} N_p = a \times \log_{10}(\Psi\text{Re} \times \text{Fr} \times \rho R_b^3/m) + b$$

was postulated and the constants a and b (slope and intercept in a log-log domain) were found empirically ($b = 2.46$ and $a = -0.872$) with a good correlation (>0.92) between the observed and predicted numbers (Fig. 13). Radius of the bowl R_b cubed was used to represent the bowl volume V_b . The graph indicates a collection of end-points produced with different mixers and different processing factors.

It was noted that the above equation could be interpreted to indicate that

$$\Delta P \sim \eta \times d^2 \times V_m/V_b$$

the net power consumption of the impeller varies directly with the fill ratio, wet mass viscosity, and the surface swept by the blades (proportional to d^2).

Wet masses produced at the same end-point (regardless of bowl and batch size, impeller speed, and moisture content) have been consistently shown to result in the same final dry granule size distribution, bulk density, flow, and mechanical strength.

Case Study IV: Landin et al. (1999)

Following the methodology developed in the previous Case Study using the same assumptions, this study was also performed on planetary mixers Collette MP20,

Table 7 The transformed dimensional matrix for case study II

	Unity matrix			Residual matrix			
	ρ	d	n	P	η	g	H
M	1	0	0	1	1	0	0
3M + L	0	1	0	5	2	1	1
-T	0	0	1	3	1	2	0

Table 8 Dimensionless Π groups^a

Π group	Expression	Definition
Π_0	$P/(\rho^1 \times d^5 \times n^3) = N_p$	Newton (Power) number
Π_1	$\eta/(\rho^1 \times d^2 \times n^1) = \text{Re}^{-1}$	Reynolds number
Π_2	$g/(\rho^0 \times d^1 \times n^2) = \text{Fr}^{-1}$	Froude number
Π_3	$H/(\rho^0 \times d^1 \times n^0) = H/d$	Geometric number (ratio of characteristic lengths)

^aFormed from the matrix in Table 7.

MP90, and MPH 200.^[48] The relevance list and dimensional matrix were the same as before, and torque measurements from torque rheometer were again used to represent kinematic viscosity (instead of dynamic viscosity) in Reynold numbers.

Fig. 14 represents the resulting regression line

$$\log_{10} N_p = a \times \log_{10}(\Psi \text{Re} \times \text{Fr} \times \rho R_b^3/m) + b$$

for the combined results from three mixers with bowl sizes 20, 90, and 200 L showed a pretty good fit to data ($r^2 > 0.95$). The values for the slope and intercept were found to be: $a = -0.68$, $b = 1280$. Data from two other mixers with bowl sizes 5 and 40 L produces lines that were significantly different from the first set of mixers. The authors explained this difference by an assumption of “different flow patterns” in the two groups of mixers.

Case Study V: Faure et al. (1999)

This study was done on Collette Gral Mixers (8, 25, 75, and 600 L) and followed the accepted—and by now, standard—methodology developed earlier.^[52] The problem with the scale-up in the Gral mixers was the lack of geometric similitude: there was significant “distortion factor” between the bowl geometries at different scales. In addition, the researchers had to take into account the lack of dynamic similitude because of

different wall adhesion and lid interference that was partially relieved by using a Polytetrafluoroethylene (PTFE) lining.

The end result of the dimensional analysis and experimental work was, again, a regression equation (Fig. 15) of the form

$$\log_{10} N_p = a \times \log_{10}(\Psi \text{Re} \times \text{Fr} \times \rho R_b^3/m) + b$$

The regression coefficient was $r^2 > 0.88$ using the data from the 8, 25 and 75-L bowls with PTFE lining, and the 600-L bowl that did not require the lining. The slope was found to be $a = -0.926$, and the intercept $b = 3.758$.

Case Study VI: Hutin et al. (2004)

In this study, the foregoing methodology of dimensional analysis was applied to a kneading process of drug-cyclodextrin complexation.^[109] Aoustin kneader with dual Z blades was instrumented for torque measurements and multiple runs were made at two scales (2.5 and 5 L).

The relevance list for this study (Table 10) differs from those discussed previously by addition of blade length as one of the crucial factors affecting the process.

Introduction of the blade length, after the proper operations with the dimensional matrix, creates another dimensionless quantity, namely, d/l , so that the resulting regression equation has the form of

$$N_p = b(\Psi \text{Re} \times \text{Fr} \times h/d \times d/l)^{-a}$$

Experiments showed that the model fits data remarkably well ($r^2 > 0.99$).

Unfortunately, the Pharmaceutical Technology journal does not grant permissions to reproduce individual graphs; therefore, an interested reader is referred to the source article to see the regression lines from this study.

Fig. 12 Case study II. Regression lines of the Newton power number on the product of Reynolds number, Froude Number, and the length ratio for three different Fielder mixers. (Reprinted from Ref.^[46], copyright 1996, with permission from Elsevier.)

Table 9 Relevance list for case study VI (Hutin et al., 2004)

Quantity	Symbol	Units	Dimensions
Net power	ΔP	Watt	$M L^2 T^{-3}$
Wet mass bulk or specific density	ρ	kg/m^3	$M L^{-3}$
Impeller radius (or diameter)	d	m	L
Impeller speed	n	rev/sec	T^{-1}
Granulation dynamic viscosity	η	Pa sec	$M L^{-1} T^{-1}$
Gravitational constant	g	m/sec^2	$L T^{-2}$
Height of granulation bed in the bowl	h	m	L

PRACTICAL CONSIDERATIONS FOR END-POINT DETERMINATION AND SCALE-UP

How to Determine an End-Point?

A wet granulation end-point should be defined empirically in terms of wet mass density and viscosity, PSD, flowability or tableting parameters (e.g., capping compression).

It is advisable to run a trial batch at a fixed speed and with a predetermined method of binder addition (for example, add water continuously at a fixed rate to a dry mix with a water-soluble binding agent).

Before adding the liquid, measure the baseline level of motor power consumption P_o or impeller torque τ_o at the dry mix stage.

During the batch, stop the process frequently to take samples and, for each sample, note the end-point values of power consumption P_e or impeller torque τ_e . For each of these “end-points,” measure the resulting wet mass density ρ . As a result, you will be able to obtain some data that will relate the

“end-point parameters” listed above with the processing variables in terms of net motor power consumption $\Delta P_m = (P_e - P_o)$ or net impeller power consumption $\Delta P_i = 2\pi \times (\tau_e - \tau_o) \times n$, where n is the impeller speed [dimension T^{-1}].

Once the desired end-point is determined, it can be reproduced by stopping the batch at the same level of net power consumption ΔP (for the same mixer, formulation, speed, batch size, and amount/rate of granulating liquid). To account for changes in any of these variables, you have to compute the Newton power number N_p for the desired end-point:

$$N_p = \Delta P / (\rho \times n^3 \times d^5)$$

In other words, if you have established an end-point in terms of some net impeller or motor power ΔP and would like to reproduce this end-point on the same mixer at a different speed or wet mass density, calculate Newton power number N_p from the given Net Impeller power ΔP , impeller speed n , blade radius d , and wet mass density ρ (assuming the same batch size),

Fig. 13 Regression graph of Case Study III. The Reynolds number Re was, in fact, a dimensional “pseudo Reynolds number” ΨRe . Data from a dual bowl Hobart AE240 planetary mixer. (Reproduced from Ref.^[49].)

Fig. 14 Regression graph of Case Study IV. The Reynolds Number Re was, in fact, a dimensional “pseudo Reynolds” number ΨRe . Data from Collette MP20, MP90, and MPH200 planetary mixers. (Reproduced from Ref.^[48].)

and then recalculate the target ΔP with the changed values of speed n or wet mass density ρ .

Wet mass viscosity η can be calculated from Net Impeller power ΔP , blade radius d , and impeller speed n , using the following equations:

$$\Delta P = 2\pi \times \Delta\tau \times n$$

$$\eta = \varphi \times \Delta\tau / (n \times d^3)$$

where $\Delta\tau$ is the net torque required to move wet mass, n is the speed of the impeller, d is the blade radius or diameter, and φ is mixer specific “viscosity factor”

relating torque and dynamic viscosity (note: the correlation coefficient φ can be established empirically by mixing a material with a known dynamic viscosity, e.g., water). Alternatively, you can use impeller torque τ as a measure of kinematic viscosity and use it to obtain a non-dimensional “pseudo-Reynolds” number, based on the so-called “mix consistency” measure, that is, the end-point torque, as described in the case studies.

Fill Ratio h/d can be calculated from a powder weight, granulating liquid density (1000 kg/m^3 for water), rate of liquid addition, time interval for liquid addition, and bowl volume V_b . The calculations are performed using the idea that the fill ratio h/d (wet mass height to blade diameter) is proportional to V/V_b , and wet mass volume V can be computed as

$$V = m/\rho$$

Fig. 15 Regression graph of Case Study V. Data from Collette Gral 8, 25, 75, and 600 liter mixer-granulators. (Reprinted from Ref.^[52], copyright 1999, with permission from Elsevier.)

Table 10 Relevance list for Hutin et al. (2004)

Quantity	Symbol	Units	Dimensions
Power consumption	P	Watt	$M L^2 T^{-3}$
Specific density	r	kg/m^3	$M L^{-3}$
Blade radius	d	M	L
Blade speed	n	rev/sec	T^{-1}
Dynamic viscosity	η	Pa sec	$M L^{-1} T^{-1}$
Gravitational constant	g	m/sec^2	$L T^{-2}$
Powder bed height	h	M	L
Blade length	l	M	L

where m is the mass (weight) of the wet mass and ρ is the wet mass density.

Now, the weight of the wet mass is computed as the weight of powder plus the weight of added granulating liquid. The latter, of course, is calculated from the rate and duration of the liquid addition and the liquid density.

Finally, following the examples discussed in the case studies, you can combine the results obtained at different end-points of the test batch or from different batches or mixer scales (assuming geometrical similarity).

Given wet mass density ρ , wet mass viscosity η , fill ratio $h/d \sim m \times V_b/\rho$, setup speed n , and blade radius or diameter d , you can calculate the Reynolds number Re (or the “pseudo-Reynolds” number) and the Froude number Fr . Then you can estimate the slope “ a ” and intercept “ b ” of the regression equation

$$N_p = b \times (Re \times Fr \times h/d)^a$$

or

$$\log N_p = \log b + a \times \log(Re \times Fr \times h/d)$$

And, inversely, once the regression line is established, you can calculate Newton power number N_p (which is the target quantity for scale-up) and net power ΔP (which can be observed in real time as a true indicator of the target end-point) for any point on the line.

ACKNOWLEDGMENT

Selected excerpts and figures from M. Levin, “Granulation: End-Point Theory, Instrumentation, and Scale-Up, Education Anytime, CD-ROM Short Course, AAPS 1999” are reprinted with permission.

APPENDIX

List of Symbols and Dimensions

a, b	Slope and intercept of a regression equation
d	Impeller (blade) diameter or radius (m); dimensional units [L]
g	Gravitational constant (m/sec ²); dimensional units [L T ⁻²]
h	Height of granulation bed in the bowl (m); dimensional units [L]

H	Bowl height (m); dimensional units [L]
l	Blade length (m); dimensional units [L]
n	Impeller speed (rev/sec); dimensional units [T ⁻¹]
P	Power required by the impeller or motor ($W = J/sec$); dimensional units [M L ² T ⁻³]
R_b	Radius of the bowl (m); dimensional units [L]
q	Binder liquid addition rate
s	Amount of granulating liquid added per unit time (kg); dimensional units [M]
t	Binder addition time (sec); dimensional units [T]
V_p	Particle volume (m ³); dimensional units [L ³]
V_m	Wet mass volume (m ³); dimensional units [L ³]
V_b	Bowl volume (m ³); dimensional units [L ³]
w	Wet mass; dimensional units [M]
ρ	Specific density of particles (kg/m ³); dimensional units [M L ⁻³]
$\nu = \eta/\rho$	Kinematic viscosity (m ² /sec); dimensional units [L ² T ⁻¹]
η	Dynamic viscosity (Pa sec); dimensional units [M L ⁻¹ T ⁻¹]
τ	Torque (N-m); dimensional units [M L ² T ⁻²]. End-point torque values were described as “wet mass consistency” numbers. Note: torque has the same dimensions as work or energy
$\varphi = \eta \times n \times d^3/\Delta\tau$	Dimensionless “viscosity factor” relating net torque $\Delta\tau$ and dynamic viscosity η
$Fr = n^2 \times d/g$	Froude number. It relates the inertial stress to the gravitational force per unit area acting on the material. It is a ratio of the centrifugal force to the gravitational force
$N_p = P/(\rho \times n^3 \times d^5)$	Newton (power) number. It relates the drag force acting on a unit area of the impeller and the inertial stress
$Re = d^2 \times n \times \rho/\eta$	Reynolds number. It relates the inertial force to the viscous force

$$\Psi Re = d^2 \times n \quad \text{"Pseudo Reynolds number"} \\ \times \rho / \tau \quad (\text{m}^3/\text{s}); \text{dimensional units } [\text{L}^{-3} \text{T}]. \text{ Note: this variable physi-} \\ \text{cally is a reciprocal of volume} \\ \text{flow rate}$$

$$Ga = Re^2 / Fr \quad \text{Galileo number}$$

World Health Organization (WHO): Global Harmonization of Requirements for Medicinal Products

Juhana E. Idanpaan-Heikkilä

World Health Organization, Geneva, Switzerland

INTRODUCTION

The World Health Organization (WHO) is an inter-governmental specialized agency of the United Nations with 193 member states. Regarding pharmaceutical and biological products, WHO has the global mandate to develop, establish, and promote quality, safety, and efficacy standards and codes of good practices for all medicinal products. Vigorous harmonization of quality, safety, efficacy, and nomenclature requirements on a worldwide basis has continued in 1998–2000 as the explicit responsibility of WHO. The content of the constitutional mandate, expertise involved, working practices and rules, consultative processes, and role of the governing bodies regarding WHO's normative work.^[1] This review gives an update on ongoing harmonization activities since 1998 and outlines the new harmonization initiatives.

INTERNATIONAL NON-PROPRIETARY NAMES (INNs)

The International Non-proprietary Names (INNs) identifies pharmaceutical substances by unique, globally recognized names. A single internationally recognized name for an active drug substance is a starting point for its pharmacopeial monograph, safe prescribing and dispensing, and easy communication among scientists and health professionals worldwide. The INN is for common use without restrictions (except as a trademark); it is distinctive in sound and spelling and not too long. In 1998–1999, WHO published more than 270 new INNs in its quarterly publication, WHO Drug Information^[2] and issued a revised Guidelines on the Use of International Non-proprietary Names (INN) for Pharmaceutical Substances.^[3] The revision of the procedure included the introduction of a service fee, improvements in Procedures to raise objections to proposed INNs, and the replacement of a recommended INN.

Naming the biotechnology-derived substances and products received increasing attention. Prevention of INNs from using trademarks has now been strengthened in collaboration with the World Intellectual Property Organization (WIPO). A new point of collaboration was the protection of INNs against misuse of Internet domain names.^[4]

INTERNATIONAL PHARMACOPOEIA—50 YEARS OLD

Publication of the International Pharmacopoeia has continued now for 50 years. Its role has been to fulfill a need in developing countries where use of less technically advanced tests using simple instrumentation is common practice for specific substances and preparations. Publishing monographs for finished products has also been useful. In 1999, the Expert Committee recommended that less-advanced methods should be developed in parallel with modern analytical techniques because in some developing countries, more sophisticated methods could be useful.^[4] Volume 5 of the International Pharmacopoeia is in print. WHO has completed monographs for several antimalarials including artemisin derivatives. Basic tests for pharmaceutical substances, medicinal plant materials, and dosage forms (including 345 tests for substances, 208 for dosage forms, and four for plant materials) were published in 1998.^[5] The 69 International Infrared Reference Spectra (IIRS) have been made available from the WHO Collaborating Centre for Chemical Reference Substances (Kungens Kurva, Sweden). The list of reference substances and infrared reference spectra is updated regularly and is now available on the World Wide Web (<http://www.who.int/dmp/irintro.htm>).

A revised guideline on Good Practices for National Pharmaceutical Control Laboratories (GPCL) was published in 1999. It takes into account guidances from ISO 17025, EN 45001, and OECD–GLP and

recommendations published by the Pharmaceutical Inspection Convention (PIC).^[4]

WHO GMP AND QUALITY ASSURANCE

In 1998, WHO began a special project to assist in implementing of GMP in member states with limited resources. Countries interested in upgrading their manufacturing have been identified, and training material on basic GMP principles has been prepared together with training modules for advanced GMP topics and inspections. Several regional training workshops for trainers in GMP have been organized, together with missions to concerned countries.^[4]

The following guidelines have been completed: GMP for Sterile Pharmaceutical Products, Guideline on Pre-Approval Inspection (before granting marketing authorization), Quality System for National GMP Inspectorate, and General Aspects of Packaging Pharmaceuticals.^[4]

In 1999, WHO published a report on the control and safe trade of starting materials for pharmaceutical products in English, French, Spanish, Russian, Chinese, and Arabic, based on recommendations from a meeting of experts in Geneva in May 1998.^[6] The meeting was inspired by several recent incidents of contamination with highly toxic solvent diethylene glycol.

Because of their increasing use worldwide, plant materials used in over-the-counter preparations, home remedies, or as raw materials for pharmaceutical preparations are receiving more and more attention. In 1998, WHO published a book, *Quality Control Methods for Medicinal Plant Materials* to fulfill the needs of quality control laboratories and to provide a basis for the development of national standards.^[7]

A compendium of WHO guidelines and related materials entitled *Quality Assurance of Pharmaceuticals*, Volume 1, was published^[8] and the next volume is in print.

Counterfeit Drugs

In 1999, WHO published guidelines on the detection and prevention of counterfeit and substandard products.^[9] Vigilance and reporting of counterfeit products to WHO were enhanced by setting up a liaison officer network among drug regulatory authorities and WHO.

THE WHO CERTIFICATION SCHEME

The WHO Certification Scheme on the Quality of Pharmaceutical Products Moving in International Commerce^[1] was used in increasing the number of

countries as a model instrument to exchange information among authorities in importing and exporting countries. In 1999, WHO completed a model certificate of analysis to be used for trade of starting materials intended for drug manufacturing, and manufacturers of pharmaceutical substances, excipients, and medicinal products.^[4]

Comparator Product System for Equivalence Testing

The use of generic pharmaceutical products has increased in many countries. Consequently, drug regulatory authorities are increasingly involved in the assessment of the scientific documentation submitted for marketing approval of generic medicinal products. WHO has stated that the quality, safety, and efficacy of a generic product must comply with the same requirements applied to the innovator.^[10] Consequently, the therapeutic equivalency and interchangeability with the innovator must be proven with valid comparative in vivo bioequivalence studies. To assist both manufacturers and drug regulators in this, WHO has developed a list of international comparator products. The information on comparator products was collected first from drug regulatory agencies, and a provisional list of candidate products was consulted with the innovator companies concerned. The companies were requested to designate the market and trademark that best represented the quality, manufacturing, and labeling of the product. The current list thus far contains 147 products from the WHO Model List of Essential Drugs, complemented with detailed instructions for use and a decision tree for special situations.^[11] The list will be updated periodically by WHO.

THE WHO MODEL LIST OF ESSENTIAL DRUGS

The Model List of Essential Drugs was created in 1975, and the most recent assessment and updating of the list took place in 1997 and 1999.^[12,13] The following additions to the list were made including aciclovir for use in herpes infections; amoxicillin + clavulanic acid for the treatment of infections resistant to the production of β -lactamase; dextrometorphan for the treatment of cough; ephedrine for treatment of hypotension in spinal anesthesia during delivery; imipenem + cilastatin for the treatment of *Pseudomonas*; ipratropium bromide for the treatment of asthma; metformin for the treatment of non-insulin-dependent diabetes; triclabendazole for the treatment of liver and lung flukes; and nevirapine and zidovudine to reduce or prevent mother-to-child transmission of HIV infection. The value of lipid-lowering

agents was discussed; however, because of their high costs, they were not included in the list, with a recommendation that each country make its own decisions for use in high-risk patient populations.^[12]

Sale and Promotion of Medical Products on the Internet

The Internet is a rapidly expanding medium that has many uses and great potential for disseminating and obtaining information regarding a variety of subjects such as new treatments, institutions offering care, and medical products available. Individuals can get this information more quickly and conveniently than in traditional ways, such as in medical journals and textbooks. Organizations, pharmaceutical companies, and individuals post and exchange information about their aims, activities, or products and sometimes offer to sell their products, including medical products. However, have the products been approved for marketing? Are they safe, effective, properly labeled, and of good quality? Reported cases show that dangerous, harmful, unreliable, low-quality, substandard, fake, counterfeit, and mislabeled products have been available on the Internet.^[14]

The World Health Assembly (the annual summit of Ministries of Health of 193 member states of WHO) recognized in May 1997 the increasing use of electronic communication by the general public to shop and gather information on health education, diseases, treatments, and medical products.^[15] The Assembly was concerned about reported cases of inappropriate use of the Internet, which had caused a potential hazard for public health, and decided to convene a WHO ad hoc working group to formulate recommendations for action. The working group met in September 1997 in Geneva and consisted of representatives of health and drug regulatory authorities, consumer groups, professional associations, the pharmaceutical industry, experts in legal and ethical matters, marketing, and other interested parties. The group reviewed the situation and made several recommendations regarding cross-border advertising, promotion, and sale of medical products. Based on these recommendations, in May 1998^[16] the World Health Assembly urged all member states to review existing legislation, regulations, and guidelines to ensure that they are applicable and adequate to cover the promotion and sale of medical products over the Internet. Member states were asked to set up monitoring and surveillance systems for the Internet. Collaboration was recommended among countries to identify difficult cases and disseminate information through WHO. The availability of scientific, validated information to consumers by competent health authorities was determined to be necessary.

The Assembly appealed to the pharmaceutical industry, health professional and consumer organizations, and other interested parties to promote the formulation and use of good information practices consistent with the principles of the WHO Ethical Criteria for Medicinal Drug Promotion; monitor and report problem cases and aspects of cross-border advertising, promotion, and sale of medical products using the Internet; and maintain legal and ethical standards in these activities.

WHO was requested to encourage the international community to formulate self-regulatory guidelines for good information practices and to develop a model guide for member states. The guide should educate and instruct people using the Internet on how to best obtain reliable, independent, and compatible information on medical products through this medium. The WHO model guide, *Medical Products and the Internet*, was published in 1999.^[17]

Biologicals

WHO's normative work for biological substances used in medicinal products, including vaccines, blood products, and diagnostic procedures, has resulted in a number of globally applicable specifications, guidelines, and guiding principles. In 1999, WHO published guidelines for the production and quality control of synthetic peptide vaccines for human use to ensure their consistent safety and efficacy.^[18] The guidelines address control of starting materials including background data on the synthesis of the peptide of interest and control of the manufacturing process and the final product. WHO requirements for tick-borne encephalitis vaccine (inactivated) were formulated to take into account current manufacturing practices and control procedures in place and to give guidance on how these practices and procedures could be updated.^[18] Requirements for hepatitis B vaccines made by recombinant DNA techniques have been amended to reflect recent developments in assay methodology, as well as for specifications for *Hemophilus* type b conjugate vaccines. Under development were guidelines for standardization and calibration of cytokine immunoassays, and requirements for tetravalent dengue vaccine (live) and oral poliomyelitis vaccine.^[18]

In 1999, WHO published requirements for production and control of *Haemophilus influenzae* type b (Hib) conjugate vaccine and the acellular pertussis component of monovalent or combined vaccines. The requirements for oral polio vaccine (OPV) were also revised in 1999, with several additions. WHO published new and replacement International Standards and Reference Materials covering a wide range of products.^[19]

WHO, ICH, AND REGIONAL HARMONIZATION

The role of WHO as an observer of the ICH and its contribution as a global, intergovernmental organization to tripartite ICH activities involving 17 WHO member states have been described in detail.^[1]

With strong support from WHO, the ICH Steering Committee decided in 1997 to accept the participation of experts from the International Generic Pharmaceutical Alliance (IGPA) and the World Self-Medication Industry (WSMI) in the designated expert working groups.^[20] This was a first step toward a more comprehensive harmonization procedure. Since 1998, WHO participated as an observer in drafting a guideline for good manufacturing practices for active pharmaceutical ingredients based on preliminary work by the Pharmaceutical Inspection Co-operation Scheme (PIC/S). Australia, China, and India, known for their extensive production of pharmaceutical substances and excipients, were invited to participate in this exercise. The draft guideline is still in development and was an ICH step 2 document in February 2000.

Because Common Technical Document (CTD) (content and format of a new drug application) was accepted as a new ICH topic in 1998, WHO asked a WHO regional adviser for pharmaceuticals from each of the six WHO regions to coordinate among ICH CTD working groups and drug regulatory authorities WHO regions.^[20] This is an important development because the CTD will undoubtedly have an impact on new drug applications in non-ICH countries and industries. The CTD expert working groups succeeded in 1999 to sign-off as step 2 document tables of contents for all three sections of the CTD, namely quality, safety, and efficacy. Significant work remains to be done, and the progress has been slowest in the quality section.

In 1999, the ICH began a major revision of its existing stability testing guideline. To make this guideline practical and useful for all countries, WHO suggested that it should address not only new molecular entities and associated drug products but also stability testing of generic pharmaceutical products in its new revised form. Furthermore, WHO proposed that it should address, in addition to its current coverage of only climatic zones I and II, the remaining critical climatic zones, namely zone III (hot/dry) and zone IV (hot/humid). The WHO guidelines on stability testing of pharmaceutical products containing well-established (generic) drug substances in conventional dosage forms cover all four climatic zones.^[21,22]

X-Ray Powder Diffractometry

Raj Suryanarayanan

College of Pharmacy, University of Minnesota, Minneapolis, Minnesota, U.S.A.

Suneel Rastogi

Forest Laboratories, Inc., Inwood, New York, U.S.A.

INTRODUCTION

X-rays are electromagnetic radiation lying between ultraviolet and gamma rays in the electromagnetic spectrum. The wavelength of the X-ray region is considered to be between 0.01 and 100 Å.^[1]

There are two broad applications of X-rays in the characterization of materials: (i) X-ray spectrometry and (ii) X-ray diffractometry. The former technique is used for chemical analysis and has found only limited use in the characterization of pharmaceuticals. On the other hand, X-ray diffractometry, by providing a means for the study of the structure of crystalline materials, is extensively used to characterize pharmaceutical solids. There are two principal applications of X-ray diffractometry. X-ray crystallography is concerned with the structure determination of crystalline phases. Single crystals are usually used for this purpose. On the other hand, in X-ray powder diffractometry, the sample is usually in the form of a powder. X-ray powder diffractometry is recognized as a powerful technique for the identification of crystalline phases. The technique can also be used for the quantitative analyses of solids. This article will be restricted to the principles and applications of X-ray powder diffractometry (XRD) in the characterization of pharmaceutical solids.

Diffraction is a scattering phenomenon. When X-rays are incident on crystalline solids, they are scattered in all directions. In some of these directions, the scattered beams are completely in phase and reinforce one another to form the diffracted beams.^[1,2] The Bragg law describes the conditions under which this would occur. It is assumed that a perfectly parallel and monochromatic X-ray beam, of wavelength λ , is

incident on a crystalline sample at an angle θ . Diffraction will occur if:

$$n\lambda = 2d \sin \theta \quad (1)$$

where d = distance between the successive planes in the crystal lattice, expressed in Å, and n = order of reflection (an integer).

X-ray patterns can be obtained using either a powder diffractometer or a camera. Currently, diffractometers find widespread use in the analysis of pharmaceutical solids. The technique is usually non-destructive in nature. The theory and operation of powder diffractometers is outside the scope of this discussion, but these topics have received excellent coverage elsewhere.^[1-4] Instead, the discussion will be restricted to the applications of X-ray powder diffractometry (XRD) in the analysis of pharmaceutical solids. The United States Pharmacopeia provides a brief but comprehensive introduction to X-ray diffractometry.^[5] The use of XRD in the physical characterization of pharmaceutical solids^[6] and in the characterization of controlled release delivery systems have been discussed earlier.^[7]

QUALITATIVE ANALYSIS

Since the X-ray diffraction pattern of every crystalline form of a compound is unique, the technique is widely used for the identification and characterization of solid phases. XRD is the technique of choice to identify different polymorphic forms of a compound (Fig. 1).^[8] It can also be used to identify the solvated and unsolvated (anhydrous) forms of a compound, provided their lattice structures are different. The technique can also reveal differences in the crystallinity of compounds. The XRD pattern of an amorphous (non-crystalline) compound will consist of one or more broad diffuse halos (Fig. 2A).^[9]

The United States Pharmacopeia contains the XRD patterns of two anhydrous forms (Form 1 and Form 2)

Some parts of this article have been reproduced from the chapter, "X-ray Powder Diffractometry," written by R. Suryanarayanan in "Physical Characterization of Pharmaceutical Solids," edited by H. Brittain. This was Vol. 70 of *Drugs and Pharmaceutical Sciences*, Editor: J. Swarbrick, Marcel Dekker, Inc., New York, 1995.

Fig. 1 X-ray powder diffraction (XRD) patterns of the different solid forms of AG337. (From Ref.^[8].)

of ampicillin, ampicillin trihydrate and amorphous anhydrous ampicillin.^[5] The powder patterns of these four solid phases reveal pronounced differences, which can form the basis of their identification.

XRD was a powerful tool for the characterization of the different solid phases of AG337 (a 5-substituted quinazolinone; dihydrochloride salt). In addition to several polymorphic forms of the anhydrate ($C_{14}H_{12}N_4OS \cdot 2HCl$), the compound existed as a hemihydrate ($C_{14}H_{12}N_4OS \cdot 2HCl \cdot 0.5H_2O$), a monohydrate ($C_{14}H_{12}N_4OS \cdot 2HCl \cdot H_2O$), and a dihydrate ($C_{14}H_{12}N_4OS \cdot 2HCl \cdot 2H_2O$).^[8] The hemihydrate, the dihydrate, and one of the polymorphic forms of the anhydrate (I_δ) had identical lattice structures (Fig. 1).

While the amorphous and crystalline solid forms of sucrose can be readily distinguished by XRD (Fig. 2A), the technique is also capable of revealing the presence of small amounts of crystalline sucrose in the presence of amorphous sucrose.^[9] This is evident from the XRD patterns of physical mixtures of amorphous and crystalline sucrose wherein the crystalline sucrose content ranged between 1 and 5 wt% (Fig. 2B).

Six crystalline solid phases of fluprednisolone and an amorphous phase were characterized using XRD, IR spectroscopy, and differential scanning calorimetry.^[10] Three of these six crystalline phases were anhydrous, two were monohydrates, and one was a tert-butylamine disolvate. The differences in the powder patterns of the phases were readily evident. This study

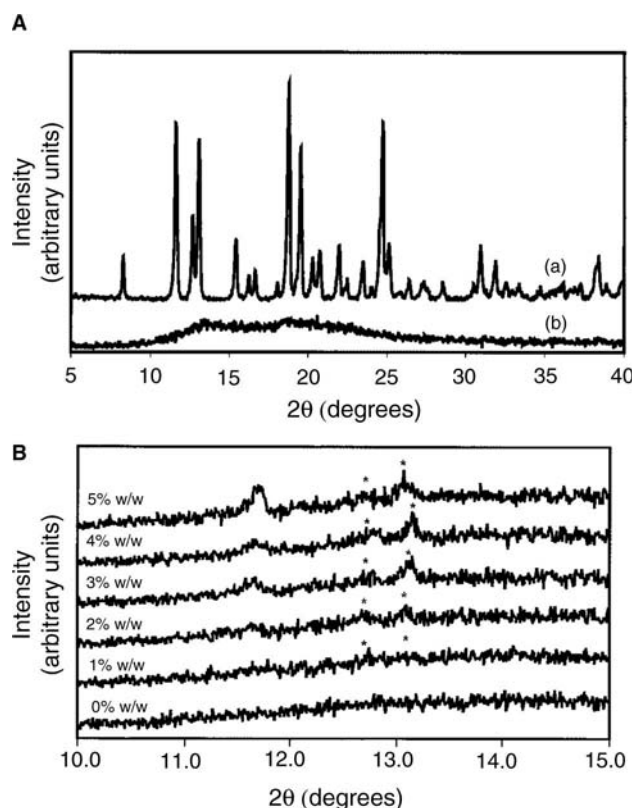

Fig. 2 (A) XRD patterns of (a) crystalline and (b) amorphous sucrose. (B) XRD patterns of the physical mixtures of crystalline and amorphous sucrose. The sucrose content ranged between 0 and 5 wt%. The 12.7 and 13.1°2θ peaks were used for the quantitative analyses. [(B) Reproduced from Ref.^[9].]

demonstrated the unique ability of XRD for the identification of (a) an anhydrous compound existing in both crystalline and amorphous states, (b) different polymorphic forms of the anhydrate, (c) the existence of solvates, where the solvent of crystallization is water (hydrate) or an organic solvent (in this case, tert-butylamine), and (d) polymorphism in the hydrate.

Reference Diffraction Patterns

The International Centre for Diffraction Data (ICDD, Newtown Square, PA) maintains a collection of single-phase X-ray powder patterns.^[11] There are separate listings of inorganic and organic compounds. The X-ray diffraction data of ibuprofen, as a representative example is given here (Table 1).

The card pattern contains the Powder Diffraction File (PDF) number (Region 1); quality mark of the data (Region 2); the chemical formula and the specimen name (Region 3); the experimental conditions under which the powder pattern was obtained and the source of the data (Region 4); physical data that

include crystallographic system, space group, lattice parameters, and interaxial angles (Region 5); general comments, Crystal Data cell (if different from that reported in Region 5); Pearson Symbol Code (PSC), Merck Index number, etc. (Region 6); and a table of interplanar spacings, relative intensities, and the Miller indices (Region 7).

There are also several indicators of the quality of the data. The highest quality data are given*. To qualify for this mark, the chemistry of the compound must be well characterized. The intensities of the X-ray lines must be measured objectively and instrumentally and there must be no unindexed, space group extinct or impurity lines. Lines with *d*-spacings of ≤ 2.50 Å must retain at least three significant digits after the decimal point. To qualify for the “i” mark, there can be a maximum of two unindexed, space group extinct or impurity lines provided none of these belong to the strongest eight. Again there must be no serious systematic errors and lines with *d*-spacings ≤ 2.00 Å must retain at least three significant digits after the decimal point. If the data are of low precision or if the data are due to a poorly characterized or multiphase system,

an “O” mark is assigned. Patterns that do not meet the criteria for “*,” “i,” or “O” are left blank. When the powder pattern is calculated from structural parameters, the pattern is marked “C.” Extensive details about the quality mark guidelines can be found in ICDD publications.^[12]

Another important database for pharmaceuticals is the Cambridge Structural Database (CSD). Maintained by the Cambridge Crystallographic Data Centre, CSD is a compilation of single-phase data containing structural information including unit cell parameters, crystal system, and space group. The structural information can be used to calculate powder diffraction patterns. The ICDD and the Cambridge Crystallographic Data Centre have a cooperative program. This allows the ICDD to calculate powder patterns for inclusion in the Powder Diffraction File, from the data recorded in the CSD.

Phase Identification in Solid Dosage Forms

In addition to the active ingredient, solid dosage forms usually contain one or more excipients. In such powder

mixtures, each crystalline phase produces its pattern independently of the other constituents in the mixture. Thus, the unique advantage of XRD is that it combines absolute specificity with a high degree of accuracy. Shell pioneered the use of XRD in the characterization of pharmaceutical dosage forms.^[13] The recent advances in instrumentation and software have substantially enhanced the utility of the technique. XRD was used to simultaneously identify the three active ingredients, acetaminophen, aspirin, and caffeine, in a commercially available tablet formulation (Excedrin®). The three active ingredients together constituted 83 wt% of the formulation.^[14] The XRD pattern contained numerous peaks in the angular range of 7–37° 2θ (Fig. 3d). In an effort to identify the components in the dosage form, the XRD patterns of acetaminophen, aspirin, and caffeine were obtained (Fig. 3a–c). Acetaminophen could be readily identified by two unique lines with *d*-spacings of 6.48 and 4.92 Å (2θ values of 13.65 and 18.00°, respectively). At these 2θ values, the XRD patterns of aspirin and caffeine contained no peaks. Similarly, aspirin could be readily identified by two unique lines with *d*-spacings of 11.54 and 3.95 Å (2θ values of 7.65 and 22.45°, respectively). Caffeine had an intense line with a *d*-spacing of 7.55 Å (2θ value of 11.70°) and two intense lines with *d*-spacings of 3.39 and 3.31 Å (2θ values of 26.25 and 26.85°, respectively). Since at these 2θ values, peaks due to aspirin and acetaminophen occurred, unambiguous identification of caffeine was not possible. An added complication was that caffeine constituted only 8.9 wt% of the formulation.

In order to identify caffeine, the XRD patterns of acetaminophen and aspirin were selectively subtracted from the XRD pattern of the formulation. The details of the pattern subtraction procedure are described in

Fig. 3 (a) The XRD pattern of acetaminophen powder. (b) The XRD pattern of aspirin powder. (c) The XRD pattern of caffeine powder. (d) The XRD pattern of a powdered tablet formulation containing acetaminophen, aspirin, and caffeine (Excedrin®). (From Ref.^[14].)

the literature.^[14] When the subtracted profile (Fig. 4a) was compared with that of caffeine (Fig. 4b), the high intensity peaks of caffeine at 11.70, 26.25, and 26.85° 2θ were readily discernible. However, an amorphous halo was observed over the angular range of 18–23° 2θ. The formulation contained numerous excipients including microcrystalline cellulose, hydroxypropyl methylcellulose, and hydroxypropyl cellulose. The XRD pattern of microcrystalline cellulose exhibited a broad halo over the angular range of 18–25° 2θ (Fig. 5c). While amorphous halos were also observed in the XRD patterns of hydroxypropyl methylcellulose (Fig. 5b) and hydroxypropyl cellulose (Fig. 5a), their angular range did not match that of the formulation

Fig. 5 (a) The XRD patterns of hydroxypropyl cellulose powder. (b) The XRD pattern of hydroxypropyl methylcellulose powder. (c) The XRD pattern of microcrystalline cellulose powder. (d) The residual XRD pattern after proportional subtraction of acetaminophen and aspirin XRD patterns from that of the powdered tablet formulation. (From Ref.^[14].)

Fig. 6 (a) The XRD pattern of chlordiazepoxide hydrochloride powder. (b) The XRD pattern of a powder mixture of chlordiazepoxide hydrochloride (5 wt%) and microcrystalline cellulose (95 wt%). (c) The XRD pattern of microcrystalline cellulose powder. (d) The residual XRD pattern after proportional subtraction of the microcrystalline cellulose XRD pattern from that of the physical mixture (b). The full scale in this case is different from that of the other three XRD patterns. (From Ref.^[14])

(Fig. 5d). Therefore, microcrystalline cellulose is likely to be the major contributor to the observed halo. Thus, XRD not only permitted simultaneous identification of all the active ingredients in the dosage form, but it also provided information about the excipients in the formulation.

The authors also evaluated the sensitivity of the method, using chlordiazepoxide HCl (hereafter referred to as chlordiazepoxide) as the model compound.^[14] While chlordiazepoxide was crystalline (Fig. 6a), microcrystalline cellulose exhibited a broad amorphous halo (Fig. 6c). Identifying chlordiazepoxide was no problem so long as its weight fraction was ≥ 0.10 . When the drug weight fraction was decreased to 0.05, its presence was not readily discernible (Fig. 6b). Using the pattern subtraction technique, the XRD pattern of microcrystalline cellulose was subtracted from the XRD pattern of the drug-microcrystalline cellulose mixture (Fig. 6d). This permitted ready identification of chlordiazepoxide (compare Fig. 6d with 6a).

Phase Transitions Induced During Processing

The components of a dosage form, both active ingredients and excipients, can undergo a variety of physical transformations during pharmaceutical processing and storage. These include polymorphic transformations, alterations in crystallinity, and changes in the state and degree of hydration. XRD is well-suited for analyses of such transformations, provided the analytes are crystalline. In most cases, the dosage forms

can be analyzed directly with minimal or no sample pretreatment. There is no need to extract the active ingredient from the dosage form, since it can be usually characterized in presence of the excipient(s). The technique will permit simultaneous identification and quantification of more than one active ingredient in formulations. Finally, XRD can provide quantitative information about the degree of crystallinity.

When theophylline monohydrate was dehydrated, it formed a metastable anhydrous phase, which then transformed to the stable anhydrate.^[15] The XRD patterns of the two anhydrate phases and the monohydrate were sufficiently different so that all three of them could be simultaneously identified in a sample (Fig. 7A). Anhydrous theophylline was granulated with an aqueous solution of PVP. During the wet-massing stage, the anhydrate transformed to the monohydrate. When the granules were dried, there was dehydration resulting in the formation of the metastable anhydrate, which then transformed to the stable

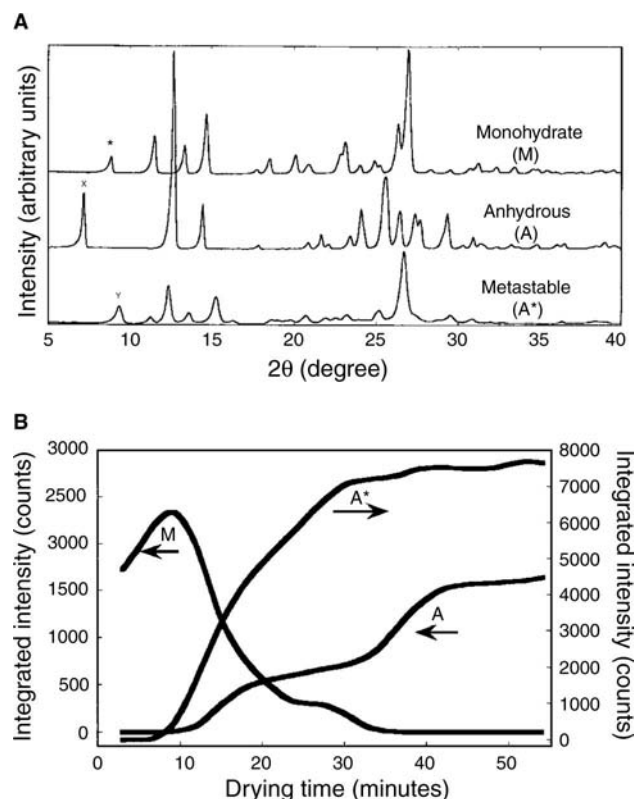

Fig. 7 (A) XRD patterns of theophylline phases. M, A, and A* refer to theophylline monohydrate, stable anhydrous theophylline, and metastable anhydrous theophylline respectively. (B) Phase transitions during the drying of theophylline granules. PVP was the granulating agent. anhydrate. All three phases were simultaneously monitored by XRD (Fig. 7B).

DEGREE OF CRYSTALLINITY

Solids may be either crystalline or non-crystalline. The crystalline state is characterized by a perfectly ordered lattice and the non-crystalline (amorphous) state is characterized by a disordered lattice. These represent two extremes of lattice order and intermediate states are possible. The term degree of crystallinity is useful in attempts to quantify these intermediate states of lattice order.

XRD is widely used to determine the degree of crystallinity of pharmaceuticals. The procedure developed by Hermans and Weidinger^[16] is based on three assumptions. First, it must be possible to demarcate and measure the crystalline intensity (I_c) and amorphous intensity (I_a) from the powder pattern. Usually, the integrated line intensity (area under the curve), rather than the peak intensity (peak height), is measured. Second, there is a proportionality between the experimentally measured crystalline intensity and the crystalline fraction (x_c) in the sample. Finally, a proportionality exists between the experimentally measured amorphous intensity and the amorphous fraction (x_a) in the sample. The degree of crystallinity (or percent crystallinity), x_{cr} , is given by the expression,

$$x_{cr} = \frac{I_c 100}{I_c + \frac{qI_a}{p}} \quad (2)$$

where p and q are proportionality constants. The values of I_a and I_c can be determined for samples of varying degrees of crystallinity. A plot of the measured values of I_a against those of I_c will result in a straight line, and the intercepts on the y- and x-axes will provide the intensity values of the 100% amorphous and 100% crystalline materials, respectively. This method was used by Nakai et al.^[17] to estimate the degree of crystallinity of lactose that had been milled for various time periods (Fig. 8). If the value of (q/p) is known, the degree of crystallinity of an unknown sample can be calculated from the experimentally determined values of I_c and I_a . The degree of crystallinity of microcrystalline cellulose and digoxin milled for various time periods were also determined.^[18,19] The problems and limitations of this method have been discussed in the literature.^[6]

A number of drugs and excipients exist in the amorphous state. However, the physical instability of amorphous compounds can lead to their crystallization resulting in partially crystalline materials. In recent

Fig. 8 A plot of the integrated amorphous intensity (I_{am}) as a function of the integrated crystalline intensity (I_c) for lactose samples milled for various time periods. (From Ref.^[17].)

years, several techniques have been developed to quantify low levels of an amorphous compound in presence of its crystalline counterpart. Using sucrose as a model compound, an XRD method was developed to detect and to quantify crystalline sucrose when it occurred as a mixture with amorphous sucrose.^[9] The XRD patterns of amorphous and crystalline sucrose were presented earlier (Fig. 2). Standards consisting of amorphous and crystalline sucrose were prepared wherein the crystalline sucrose content ranged between 1 and 5 wt%. The sum of the background subtracted integrated intensities of the 12.7° 2θ (6.94 \AA) and 13.1° 2θ (6.73 \AA) peaks of sucrose (these peaks have been marked with an asterisk in Fig. 2) were linearly related to the weight percent of sucrose (Fig. 9).

The limits of detection and quantitation of crystalline sucrose were determined to be 0.9 and 1.8 wt% respectively. Water sorption and FT-Raman spectroscopy also appear to be very sensitive with detection possible down to levels of 1 wt%.^[20,21]

PHASE QUANTIFICATION (QUANTITATIVE ANALYSIS)

The Direct Method (No Internal Standard)

Alexander and Klug developed the theoretical basis of the quantitative analyses of powder mixtures.^[3] Although a powder mixture may be composed of several components, it can be regarded as being composed

Fig. 9 Plot of the sum of the intensities of the 12.7 and 13.1° 2θ peaks as a function of the weight percent of crystalline sucrose in mixtures of amorphous and crystalline sucrose. (From Ref.^[9].)

of just two components: Component 1 (which is the unknown) and the sum of the other components (which is designated as the matrix). The relationship between the intensity of peak i of the unknown component (I_{i1}) and its weight fraction (x_1) in the mixture is given by the equation:

$$I_{i1} = \frac{Kx_1}{\rho_1[x_1(\mu_1^* - \mu_M^*) + \mu_M^*]} \quad (3)$$

where K is a constant, ρ_1 is the density of Component 1, and μ_1^* and μ_M^* are the mass attenuation coefficients of Components 1 and the matrix respectively. The mass attenuation coefficient of a substance is the weighted average of the mass attenuation coefficients of its constituent elements.

Let us first consider a two-component mixture, where $\mu_1^* \neq \mu_M^*$. One example is a mixture of the anhydrous and hydrated forms of a compound. It is first necessary to determine the intensity of peak i of a sample consisting of only the analyte $[(I_{i1})_0]$. Next, Eq. (3) is modified so that the relative intensity of the XRD peak of Component 1 [expressed as $[(I_{i1})/(I_{i1})_0]$] is expressed as:

$$\frac{I_{i1}}{(I_{i1})_0} = \frac{x_1\mu_1^*}{x_1(\mu_1^* - \mu_M^*) + \mu_M^*} \quad (4)$$

It is possible to calculate the mass attenuation coefficients of the analyte and the matrix based on their chemical compositions.^[2] This enables the calculation of the relative intensity $[(I_{i1})/(I_{i1})_0]$ as a function of the weight fraction of the analyte in the mixture and thus generate a theoretical curve. This eliminates the need for the preparation of experimental standard curves. An added advantage of this approach is that there is no requirement of an internal standard.

This approach was used to determine the weight fractions of anhydrous carbamazepine and carbamazepine dihydrate when they occurred as mixtures.^[22] Based on the mass attenuation coefficients of the anhydrate and the dihydrate, the intensity ratios $[I_{i1}/(I_{i1})_0]$ were calculated as a function of the anhydrate content in the mixture (the line in Fig. 10). These were in good agreement with the experimentally obtained values of $[I_{i1}/(I_{i1})_0]$.

A simpler system is a two component mixture, where $\mu_1^* = \mu_M^*$. This occurs when the analyte and the matrix have the same molecular formula, as in polymorphic mixtures. In such cases, Eq. (4) reduces to:

$$\frac{I_{i1}}{(I_{i1})_0} = x_1 \quad (5)$$

Therefore a plot of the relative intensity as a function of the analyte weight fraction would be linear. This approach was used to determine the weight fractions of anhydrous α -carbamazepine and β -carbamazepine when they occurred as mixtures.^[23] While studying the polymorphism of 1,2-dihydro-6-neopentyl-2-oxonicotinic acid, Chao and Vail^[24] used XRD to quantify Form I in mixtures of Forms I and II. They estimated that Form I levels as low as 0.5 wt% can be determined by this technique. Similarly the

Fig. 10 The relative intensity of the 6.78 Å line of anhydrous carbamazepine (β -form) as a function of its weight fraction in binary mixtures of anhydrous carbamazepine (β -form) and carbamazepine dihydrate. The line is based on theoretical values, while the data points are experimental measurements. (From Ref.^[22].)

α -inosine content in a mixture consisting of α - and β -inosine was achieved with a detection limit of 0.4 wt% for α -inosine.^[25]

Internal Standard Method

In this method, an internal standard is added, and its weight fraction is maintained constant in all the mixtures. This method was used to simultaneously quantify the S(+)-enantiomer and the racemic compound of ibuprofen.^[26]

Selection of Internal Standard

Success in quantitative XRD may hinge on the selection of an appropriate Internal Standard. The following properties are desired in an internal standard.^[13]

- (i) The compound must have high crystal symmetry so that strong, but few, diffraction peaks are produced.
- (ii) The high-intensity lines in the analyte and the internal standard that are to be used for quantitative purposes should not overlap with one another, but they should be close to each other.
- (iii) The density of the internal standard should be close to that of the system ingredients so that homogeneous mixtures can be prepared for analysis.
- (iv) The internal standard must be chemically stable in the experimental system.

When dealing with organic pharmaceutical systems, an organic internal standard is preferred. Since the XRD patterns of organic compounds usually contain numerous lines, it might not be possible to identify lines unique to the analyte and the internal standard that are completely separated from one another. Therefore, inorganic compounds such as corundum (α -Al₂O₃), silicon, lithium fluoride, and zinc oxide are often used as internal standards. Methenamine, an organic compound, has several of the properties desired in an internal standard.^[13] However, it has not found widespread use in the analyses of pharmaceuticals.

Whole Powder Pattern Analyses

In the pharmaceutical community, quantitative analyses has conventionally been based on the intensity of a characteristic peak of the analyte. It is now recognized that phase quantification will be more accurate if it is based on the *entire* powder pattern.^[27,28] This forms the basis for the whole-powder-pattern analyses method developed in the last few decades. Of the available methods, the Rietveld method is deemed the most powerful since it is based on structural parameters. This is a whole-pattern fitting least-squares refinement technique that has also been extensively used for crystal structure refinement and to determine the size and strain of crystallites.

Table 2 Measured composition of carbamazepine mixtures and the residuals obtained by the Rietveld analysis

^aWeighted profile residual.
(From Ref.^[29].)

Simultaneous quantitative analyses, of complex pharmaceutical mixtures, has been accomplished by the Rietveld method.^[29] Using lithium fluoride as an internal standard, mixtures consisting of anhydrous β -carbamazepine, anhydrous α -carbamazepine, and carbamazepine dihydrate were subjected to quantitative analyses (Table 2). When the analyte concentration was high ($\geq 20\%$), the method was accurate, with a relative error $< \pm 5\%$. However, when the analyte concentration was low ($< 5\%$), the method lacked accuracy.

NON-AMBIENT XRD

Conventionally, XRD patterns are obtained at room temperature under ambient conditions. Variable temperature XRD is a technique where XRD patterns are obtained while the sample is subjected to a controlled temperature program. It is also possible to control the environment and maintain the sample under the desired relative humidity. Recent advances in commercially available instrumentation have greatly facilitated the study of pharmaceutical systems under non-ambient conditions. Experiments can be carried out both at elevated temperatures and under subambient conditions.

High Temperature XRD

In the characterization of pharmaceutical systems, high temperature XRD has been used extensively.

The phase transitions of theophylline monohydrate were discussed earlier in the section dealing with Phase Transitions Induced During Processing (Fig. 7). High temperature XRD was used to investigate the dehydration of theophylline monohydrate (Fig. 11). This technique revealed that dehydration resulted in a metastable anhydrous phase, which then transformed to the stable anhydrate.^[30] Theophylline has been in widespread use for many years and its solid-state properties have been the subject of numerous investigations. Without high temperature XRD, it is unlikely that this metastable phase would have been identified.

Kinetics of Solid-State Reactions

Solid-state reactions in pharmaceuticals can be broadly classified into chemical decompositions and physical transformations. The chemical decomposition of drugs has received adequate attention in the pharmaceutical literature. The active ingredient in a solid dosage form can also undergo a variety of physical transformations including polymorphic transitions, alterations in degree of crystallinity, and alterations in degree of solvation. These transformations can affect pharmaceutically important properties such as solubility, stability, powder flow, and tableting behavior, which ultimately can cause variations in the performance of the product. There are strict pharmacopeial standards, which govern not only the chemical purity of drugs and excipients, but also the drug content in dosage forms. On the other hand, very few compounds have

Fig. 11 High temperature XRD of theophylline monohydrate. XRD patterns were obtained at the temperatures indicated in the figure. The “*”, “+,” and “o” marks indicate peaks unique to metastable anhydrous theophylline (referred to as A* in Fig. 7), stable anhydrous theophylline (A in Fig. 7), and theophylline monohydrate (M in Fig. 7) respectively. (Adapted from Ref.^[30])

pharmacopeial standards that govern their physical form. However, it is increasingly recognized that the physical form of a compound and physical transformations in a dosage form can profoundly affect product performance. An added complication is that conventional analytical techniques such as HPLC, which are used for monitoring chemical decomposition reactions are unsuitable to monitor solid-state physical transformations. This is because of their inability to distinguish between the different solid forms of a compound. Both chemical decomposition as well as physical transitions can occur simultaneously during the processing or storage of solid formulations. Therefore, it would be ideal if an analytical technique can simultaneously monitor both types of transformations. XRD is one such technique.

Conventionally, thermoanalytical techniques, specifically differential scanning calorimetry and thermogravimetric analysis, have been used to investigate the kinetics of solid-state reactions. These techniques have several limitations. They do not unambiguously identify crystalline phases and are incapable of providing quantitative information about the degree of crystallinity. Intermediate phases, if formed, may not be readily identified. The techniques may therefore be unsuitable for discerning the reaction mechanism. When two or more gaseous products are simultaneously evolved, thermal analysis alone is not very helpful in the study of reaction kinetics. In such cases, thermal analysis should be used in conjunction with other techniques for evolved gas analysis (e.g. infrared spectroscopy, mass spectroscopy, or gas chromatography). It is often realized that solid-state reactions take place through complex mechanisms involving intermediates and the same end product is obtained through multiple pathways. In such cases, thermoanalytical techniques yield complex profiles because of overlapping thermal events. Often, it is difficult to separate the reaction steps and study the kinetics of the individual steps. XRD does not suffer from these limitations and can therefore serve as an excellent complement to thermoanalytical techniques. Recent advances in instrumentation have enabled simultaneous and independent control of the temperature and the water vapor pressure in the sample chamber.

The dehydration kinetics of theophylline monohydrate ($C_7H_8N_4O_2 \cdot H_2O$) and ampicillin trihydrate ($C_{16}H_{19}N_3O_4S \cdot 3H_2O$) were studied by XRD.^[31] Dehydration of theophylline monohydrate resulted in a crystalline anhydrous phase, while the ampicillin trihydrate formed an amorphous anhydrate. In the case of theophylline, simultaneous quantification of both the monohydrate and the anhydrate was possible. By carrying out the reaction at several temperatures, the activation energy for the dehydration reaction was determined.

The enantiomers of pseudoephedrine were observed to react in the solid state to form the racemic compound.^[32] While the powder patterns of the

enantiomers were identical, the racemic compound exhibited a different powder pattern. XRD permitted the simultaneous quantification of the disappearance of the enantiomers and the subsequent appearance of the racemic compound. The rate of disappearance of the enantiomers followed a diffusion-controlled reaction model. During the kinetic experiment, the sum of the weight fractions of the enantiomers and the racemic compound progressively decreased from an initial value of unity, suggesting the formation of an intermediate non-crystalline phase. This was confirmed by a steady increase in the background counts in the powder pattern.

The sweetener aspartame exists as a hemihydrate ($C_{14}H_{18}N_2O_5 \cdot 0.5H_2O$; ASH), under ambient conditions. When heated, ASH converted to aspartame anhydrate (ASA), which on further heating decomposed to form a diketopiperazine (DKP) derivative.^[33] The XRD patterns of ASH, ASA, and DKP showed pronounced differences (Fig. 12). XRD was used to simultaneously quantify the (i) disappearance of ASH and appearance of ASA in the first reaction and (ii) disappearance of ASA and appearance of DKP in the second reaction. For studying the kinetics of the first reaction, the peaks unique to ASH at 15.9 and 16.4° 2θ and the 17.1° 2θ peak of ASA were used. For the second reaction, the sum of the integrated intensities of the peaks at 10.2, 11.0, and 11.8° 2θ of ASA and the 13.0° 2θ peak of DKP were used. While the dehydration of ASH appeared to follow first-order kinetics, the cyclization of ASA was a nucleation-controlled process. Figs. 13 and 14 contain the dehydration and cyclization data at 118 and 180°C respectively. Since the concentrations of the crystalline reactant as well as the product were simultaneously monitored, mass balance calculations of the crystalline phases were possible at each time point. The reaction

Fig. 12 XRD patterns of aspartame hemihydrate (ASH), aspartame anhydrate (ASA) and diketopiperazine derivative (DKP). “*,” “o” and “+” denote the peaks unique to aspartame hemihydrate, aspartame anhydrate, and diketopiperazine derivative respectively. (From Ref.^[33])

Fig. 13 Weight fractions of ASH and ASA as a function of time following storage of ASH at 118°C. The curves are drawn only to assist in visualizing the trends. (From Ref.^[33].)

rate constants were obtained at several temperatures, which permitted the calculation of the activation energies of dehydration and cyclization from the Arrhenius plots.

Drug–Excipient Interactions

XRD is an excellent technique to study drug–excipient interactions, provided the drug and the excipients are crystalline. In a solid mixture, the powder pattern of each crystalline phase is produced independently of the other constituents. Thus the diffraction pattern of a powder mixture will be the summation of the diffraction patterns of the individual constituents. If the drug–excipient interaction results in a crystalline product, this will be characterized by the appearance of new peaks in the powder pattern. However, if the interaction results in an amorphous product, this will become evident from the broad halos in the pattern.

Fig. 14 Weight fractions of ASA and DKP as a function of time, following storage of ASA at 180°C. (From Ref.^[33].)

Thus, irrespective of the nature of the product phase, XRD is capable of revealing such interactions.

Low Temperature XRD

The use of a cooling accessory permits XRD patterns to be obtained under subambient conditions. In pharmaceutical systems, the greatest utility of the technique is to monitor the crystallization of solutes in frozen solutions. Conventionally, differential scanning calorimetry has been the most popular technique for the characterization of frozen systems. However, as mentioned earlier, this technique has some drawbacks: (i) It does not enable direct identification of crystalline solid phase(s). Moreover, it is difficult to draw any definitive conclusions about the degree of crystallinity. (ii) The interpretation of DSC curves is very difficult if there are overlapping thermal events. Low temperature XRD was found to be an excellent complement to differential thermal analysis in the characterization of water–glycine–sucrose ternary systems.^[34]

When sodium nafcillin solutions were frozen, the solute did not crystallize.^[35] However, annealing caused solute crystallization. It was also possible to monitor the amount of sodium nafcillin crystallizing as a function of annealing time. XRD was also useful to characterize the behavior of buffer solutions. While disodium hydrogen phosphate crystallized when an aqueous solution was frozen, the presence of monosodium hydrogen phosphate inhibited the crystallization of the former.

In situ freeze-drying

The low temperature stage of the X-ray powder diffractometer was modified so that the sample chamber could be evacuated. As a result, the entire freeze-drying process was carried out in situ in the sample chamber of the XRD. The advantage of such a set-up is that the alterations in the solid state *during* the various stages of the freeze-drying process (cooling, primary, and secondary drying) were monitored.^[36] As mentioned earlier, annealing of frozen aqueous solutions of sodium nafcillin resulted in the crystallization of sodium nafcillin hydrate (the hydrate stoichiometry was not known). During the primary drying, there was partial dehydration resulting in the formation of partially crystalline sodium nafcillin hemihydrate (Fig. 15). It was possible to simultaneously monitor the disappearance of sodium nafcillin hydrate as well as the appearance of sodium nafcillin hemihydrate (Fig. 16). XRD revealed that this reaction was complete in about 40 min. The technique was also used to monitor the phase transitions during the freeze-drying of mannitol.

Fig. 15 The XRD patterns of (a) “as is” sodium nafcillin, (b) frozen solution of sodium nafcillin (40 wt%) annealed at -4°C for 1 h, and (c) after freeze-drying the annealed system. The “as is” sodium nafcillin was a monohydrate. Annealing is believed to result in the crystallization of a higher hydrate of sodium nafcillin (unknown stoichiometry). The freeze-dried material was partially crystalline sodium nafcillin hemihydrate. (From Ref.^[35])

Implications in the Design of Freeze-Dried Formulations

Most solid-state characterization studies investigate the starting material and the freeze-dried end product. It will be useful and relevant to study alterations in the solid state *during* the different stages of the freeze-drying process, and this is enabled by low temperature XRD. The physical characterization of the phases at

Fig. 16 Real time monitoring of the phase changes during the freeze-drying of sodium nafcillin by in situ XRD. The disappearance of sodium nafcillin hydrate (“Hydrate”) and the appearance of sodium nafcillin hemihydrate (“Hemihydrate”) were simultaneously quantified. The curves were drawn to assist in visualizing the trends. (From Ref.^[36])

different stages of freeze-drying will not only aid in the optimization of the freeze-drying cycle, but will also facilitate the production of formulations that are physically and chemically stable.

ISSUES AND CHALLENGES IN XRD

Most materials of pharmaceutical interest are organic compounds. Jenkins has comprehensively discussed the problems associated with the X-ray diffractometric analysis of organic materials:^[37] 1) The unit cells of organic compounds are often large, resulting in low angle lines (large d -spacings). The accuracy of d -spacing data tends to decrease as the d -spacing increases, particularly when the d -spacing value is higher than 8 \AA ; 2) The unit cells are often of low symmetry resulting in complex powder patterns; 3) Since organic compounds usually have low mass attenuation coefficients, the X-rays can penetrate deep into the specimen leading to large beam transparency errors; and 4) Finally, organic compounds are especially prone to preferred orientation (preferred orientation is discussed in the following section).

Sample Preparation

There are many different methods of sample preparation. Most of the sample holders contain a cavity into which the powder sample is filled, usually from the top. However, the side-loading (also referred to as side-drift) method is considered the best packing method.^[1,38] Unfortunately, many commercial sample holders do not permit sample filling by this method. As a result, holders have been specially fabricated for this purpose.^[23] Since organic compounds predominantly consist of atoms with low atomic numbers, there will be significant penetration of X-rays. This can result in peak displacement as well as broadening. Detailed information on sample preparation is available in the literature.^[4]

When only a very small amount of powder sample is available, the use of a low-background (also referred to as zero background) support is advisable. The support is a quartz or silicon plate cut along a non-diffracting crystallographic direction, which is then polished.^[1] This results in a very low background and improves the signal-to-noise ratio and enables XRD patterns to be obtained with extremely small amounts of sample.

Sources of Error

There are numerous sources of error in XRD. Two of these are discussed hereafter.

Fig. 17 The structural makeup of solids. (From Ref.^[1].)

Preferred Orientation

Reliable and reproducible results can only be obtained if the sample is prepared carefully. When a sample is packed in an X-ray holder, the distribution of crystal orientations can be non-random, and this condition is referred to as preferred orientation. Jenkins and Snyder^[1] have elegantly illustrated this point in Fig. 17. Atoms bond together, in a unique manner, to form unit cells. If the unit cells are grouped so as to have long-range order, a crystalline material is obtained. In the absence of long-range order, the material is amorphous (non-crystalline). A powder sample is composed of

crystallites. When the crystallites in a sample are oriented in some particular (non-random) manner, they are said to exhibit preferred orientation.^[1] Ideally, random orientation of individual crystallites is desired. It is recognized that preferred orientation is a commonly encountered condition in powdered samples.^[2]

Grinding the sample and thereby reducing the particle size can decrease preferred orientation. However, grinding can cause lattice disorder (decrease in crystallinity) and also induce other undesirable transitions, such as polymorphic transformations. Moreover, when the particle size is very small, particle size induced peak broadening can be observed. This effect, observed when the particle size is $<10,000 \text{ \AA}$ ($1 \mu\text{m}$), is simply a consequence of the limited number of planes that are diffracting X-rays (Fig. 18). The particle (crystallite) size is related to the X-ray line width according to the Scherrer Eq. (1). It is important to recognize the fact that line broadening can be brought about by a loss in crystallinity as well as a decrease in particle size. In the pharmaceutical literature, there is a tendency to automatically attribute line broadening to loss in crystallinity. Such a conclusion, while usually correct, can be occasionally erroneous.

Measurement of Line Intensity

When measuring intensity, the integrated line intensity (peak area) and not the maximum intensity (peak height) must be measured. Variations in lattice strain and particle size can significantly influence the line shape, but their effect on the integrated intensity will generally be minimal.^[2]

Other Sources of Error

There are numerous other sources of error that are particularly relevant while conducting quantitative XRD studies. These are discussed in detail in the literature.^[1-3,6]

ACKNOWLEDGMENT

We thank Mr. Rahul Surana for his assistance in the preparation of the manuscript.

INTRODUCTION

Dispersion systems represent an important class of pharmaceutical dosage forms such as emulsions, suspensions, microspheres, liposomes, and nanoparticles. The medium of these systems is mainly aqueous in nature and the dispersed phase can be either solid particles or immiscible liquid droplets. Electrical charges are developed by several mechanisms at the interface between the dispersed phase and the aqueous medium.^[1] The two most common mechanisms are the ionization of surface functional groups and the specific adsorption of ions. These electrical charges play an important role in determining the interaction between particles of the dispersed phase and the resultant physical stability of the systems, particularly for those in the colloidal size range. For dispersed systems which are used as drug carriers, i.e., liposomes and microparticles, their *in vivo* fate and therapeutic efficacy are both affected by these surface charges. Therefore, the understanding of this electrical phenomenon becomes essential in developing these systems.

The presence of these surface charges influences an uneven distribution of charges (ions) surrounding the particle and the development of an electrical potential (or an electrical field) between the surface and the electrically neutral bulk-solution phase of the system. The surface charge and the counterions in its vicinity give rise to an electric double layer as shown in Fig. 1. The double layer is divided into two parts separated by a plane called the Stern layer which is located at about a hydrated-ion radius from the surface. Usually, the number of ions in the Stern layer is smaller than that needed to achieve neutralization of the surface charge and the balance of the neutralization occurs in a Gouy–Chapman layer outside the Stern layer. The surface potential (ψ_0) and the Stern potential (ψ_d) are not readily measured experimentally; instead, the potential between a stationary fluid layer enveloping the particle and the bulk-solution phase can be determined by measuring the mobility of the particle in an applied electrical field. The potential between the tightly bound surface liquid layer (shear plane) of the particle and the bulk phase of the solution is called

zeta potential (ζ). It can provide a measure of the net surface charge on the particle and potential distribution at the interface. Zeta potential serves as an important parameter in characterizing the electrostatic interaction between particles in dispersed systems and the properties of the dispersion as affected by this electrical phenomenon.

METHOD AND INSTRUMENTATION

Microelectrophoresis

The most common method for determining the zeta-potential is the microelectrophoretic procedure in which the movements of individual particles under the influence of a known electric field are followed microscopically. The zeta potential can be calculated from the electrophoretic velocity of the particles using the Helmholtz–Smoluchowski equation,

$$U_p = V_p E = \zeta \epsilon \eta \quad (1)$$

where U_p is the electrophoretic mobility, V_p is the electrophoretic velocity, E is the electric-field strength, ζ is the zeta potential, ϵ is the permittivity, and η is the viscosity of the medium.

It is important to realize that the observed electrophoretic migration is the sum of two contributions, one of which is the electro-osmotic flow of the medium through the cell. The glass of the sample cell generally bears negative charges, so that a diffuse layer of cations exists adjacent to them. This sets up an electro-osmotic flow through the cell (with or without particles). This flow has its maximum value at the center, since the layer of fluid adjacent to the walls is stationary. The particles tracked at the center of the cell therefore possess the maximum increment in velocity because of the electro-osmotic flow. Since there is no net liquid flow through the closed cell, a back-pressure builds up which causes fluid flow in the reverse direction in the core of the cell. In the steady state, these flows balance, giving rise to a velocity profile as shown in Fig. 2. Therefore, the tracking of particles

Fig. 1 A schematic representation of the electric double layer around a particle with negative surface charges and electrical potentials surrounding the particle.

at a location where the medium experiences no net flow becomes important in yielding an accurate electrophoretic mobility measurement. A velocity profile has been derived for the liquid contained in a cylindrical electrophoretic cell. The location with zero liquid flow is shown to be 14.6% of the cell diameter inside the surface of the capillary. The location of the surface of zero liquid flow in cells of rectangular cross section has also been determined. For a cell in which the direction of migration is relatively long compared to the width of the cell, the surface with zero liquid flow lies 21.1% of the cell depth above the bottom and below the top of the working compartment. Experimentally, particles tracked at these positions of the sample cell will display their mobility uncomplicated by the electro-osmotic effect.

The rate of particle migration can be determined by measuring with a stopwatch the time required for a particle to travel between the marks of a calibrated graticule in the microscope eyepiece. Since many particles are usually measured in order to get good statistical results, the measurement of a sample may take 30 min or even longer. As the time of measurement

Fig. 2 The velocity profile of fluid flow in an electrophoretic cell.

increases, however, the susceptibility to errors also increases. For example, a long measurement time will cause convection currents generated by heating of the sample, air-bubble formation, settling of particles, and electrode reactions. These potential errors can be avoided if the measurement is taken much more quickly without loss of accuracy. A rotating prism method employed by the Lazer Zee Meter (Model 50,1 Pen Kem, Inc.), allows the operator to measure more than 10 particles simultaneously. Data are thereby attained more rapidly and, consequently, with fewer time-dependent errors. Fig. 3 shows a diagram of light paths in the rotating prism method.^[2] The microscope is focused on the stationary layer of the cell (with no fluid flow). Special cylindrical optics compress the laser beam into an illumination sheet of laser light. A vertical adjustment is provided to vary the height so that it coincides with the focal plane of the microscope. A cube prism inside the microscope causes the viewed image to translate at a rate proportional to the prism's speed of rotation. The applied electric field causes the particle to move at an electrophoretic velocity proportional to the mobility and the applied voltage. Adjustment of the potentiometer causes the prism to rotate at a rate proportional to potentiometer voltage times applied voltage. When the image velocity caused by prism rotation is equal and opposite to the mean electrophoretic velocity, the cloud of particles appears stationary. The applied voltage is therefore proportional to the mean particle electrophoretic mobility. The mobility value is scaled by an appropriate constant in the digital meter and the computed zeta potential is displayed on the 3-digit readout.

In spite of a major improvement gained from the rotating prism method, there are still serious limitations in the use of microelectrophoresis in determining zeta potential. First, this technique cannot be applied to dense dispersions, i.e., the number density of the particles must be very low. This can sometimes, but not always, be remedied by filtering the sample and diluting a small amount of the original dispersion with a large volume of filtrate. Second, it cannot be applied

Fig. 3 A diagram of light paths in the rotating prism method of microelectrophoretic measurement.

to particles less than about $0.2\text{ }\mu\text{m}$ in diameter because they are not easily visible in the ultramicroscope, though the particle-size range may be extended by adsorbing the colloidal particles (i.e., protein molecules) on suitable carrier particles. An additional and unresolvable problem with very small particles is the blurring effect imparted by Brownian motion. Furthermore, the microelectrophoretic technique cannot be used to determine mobility distributions or to separate multimodal mobility distributions.

Electrophoretic Light-Scattering^[3-5]

Electrophoretic light-scattering is a technique which determines the electrophoretic velocities by measuring the Doppler shifts of scattered laser light. The electrophoretic mobility can be expressed by

$$U_p = \Delta\nu\lambda_0/2nE\sin(\theta/2) \quad (2)$$

where U_p is electrophoretic mobility, $\Delta\nu$ is the Doppler frequency shift, λ_0 is the wavelength of the laser in a vacuum, n is the index of refraction of the medium, E is the electric field applied, and θ is the scattering angle. Since a He-Ne laser light has a frequency of about 6.0×10^{14} , a direct measurement of frequency shifts ranging from zero to several hundred Hz may be problematic because of the difficulty in measuring a small difference between large quantities. However, this can be overcome by using the principle of heterodyning, which measures the difference in frequency resulting from a reference beam and the Doppler-shifted beam.

When the Brownian motion of the particles is negligible, the power spectrum which is generated by the autocorrelation function of the scattered light has a very narrow peak. However, the actual spectral peak has considerable line width attributable to the Brownian motion of the particles and a distribution of electrophoretic mobilities. The separation of these two sources of spectral-peak broadening is critical because, without such a separation, a measurement of electrophoretic mobility at a single angle provides information only about the peak position (Doppler shift). The shape of the peak (Doppler broadening), being attributable to either of the two effects, cannot be interpreted with a single-angle measurement. Simultaneous multiple-angle measurements allow peak shapes to be analyzed to give accurate measurement of the electrophoretic mobility and the subsequent determination of zeta potential according to the Helmholtz-Smoluchowski equation [Eq. (1)].

The DELSA 440 (Coulter Scientific Instruments) is a laser-scattering particle electrophoretic analyzer that measures the electrophoretic mobility distribution and

zeta-potential distribution.^[6] This instrument provides simultaneous measurements of line widths at four different angles so that the motion of the particle can be decomposed with high resolution into components caused by electrophoretic and diffusional motions. Therefore, particle sizing can also be carried out by the same instrument simultaneously with electrophoretic mobility determinations. Fig. 4 presents a schematic diagram of the DELSA 440 system. Other commercially available electrophoretic analyzers using the laser light-scattering principles are the Zetasizer 3 (Malvern Instruments), ZetaPlus (Brookhaven Instruments), System 3000 (PenKem, Inc.), and NICOMP 380/ZLS (Particle Sizing Systems).

Electrokinetic Sonic Analysis^[3,6,7]

When a colloidal dispersion is subject to ultrasonic waves, a density difference between the dispersed phase and the continuous phase will cause relative motion between the particles and the surrounding fluid. This relative motion means that there will be a periodic interchange of the charged particle surface and the oppositely charged counter-ions in the electric double layer. This interchange results in the development of an alternating dipole at the frequency of the applied ultrasound wave. This effect is termed the ultrasound vibration potential (UVP). The UVP effect in colloids is also referred to as the colloid vibration potential or CVP. An effect opposite that of CVP is generated, when an alternating electric field is applied to a colloidal dispersion, creating an acoustic wave which, by means of a piezoelectric device, may be transduced into an alternating potential of a certain amplitude, depending on the dispersion and the electric double-layer properties. This is called the electrokinetic sonic amplitude (ESA). These two phenomena are both known as electro-acoustic effects. The magnitude of these effects is directly proportional to the electrophoretic mobility of the particles. The mobility determined by either electro-acoustic effect is the dynamic or AC mobility of the particle.

The dynamic mobility which is determined by the electro-acoustic effects differs from the low-frequency or DC mobility that is determined by electrophoresis

Fig. 4 A schematic diagram of the DELSA 440 system.

because of the effects of particle inertia which cause particle velocities in an alternate field to become out of phase with the applied field. The higher the frequency, the greater is the phase lag between the particle and the applied field. Dynamic mobility (U_d) is a function of frequency, particle size, particle density, and particle zeta potential. These inertial effects arise in both ESA and CVP measurements. In the case of spherical particles with thin double layers and low zeta potential, the equation below can be applied:

$$U_d = (\epsilon\zeta/\eta)G(\alpha) \quad (3)$$

where $G(\alpha)$ is the inertial term. The formula for dynamic mobility is identical to the well-known Helmholtz–Smoluchowski equation [Eq. (1)] for DC electrophoretic mobility except for the $G(\alpha)$ term.

A linear relationship exists between the ESA or CVP amplitude and the volume fraction of the suspended particles. At relatively high-volume fractions, hydrodynamic and electric double-layer interactions lead to a non-linear dependence of these two effects on volume fraction. Generally, non-linear behavior can be expected when the electric double-layer thickness is comparable to the interparticle spacing. In most aqueous systems, where the electric double layer is thin relative to the particle radius, the electro-acoustic signal will remain linear with respect to volume fraction up to 10% by volume. At volume-fractions that are even higher, particle-particle interactions lead to a reduction in the dynamic mobility.

The commercial systems for zeta-potential determination using these electro-acoustic effects are typified by the AcoustoSizer 8000 (Matek Applied Sciences) consisting of five main components (Fig. 5). The synthesizer produces a continuous sinusoidal voltage which feeds into the gated amplifier. This creates a sinusoidal voltage pulse across the cell which contains the dispersion. The resulting ESA sound waves are

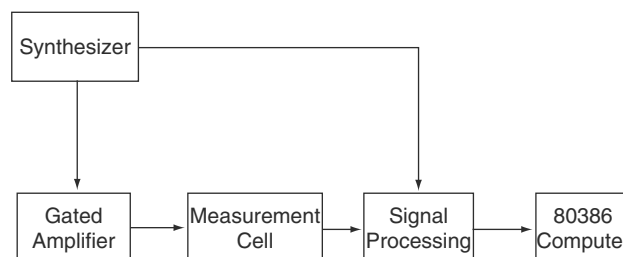

Fig. 5 An AcoustoSizer signal processing block diagram.

converted by a pressure transducer in the cell to an electrical signal, which then passes to the signal processing electronics. The electronics extract the amplitude and the phase of the ESA signal, storing them in the computer housed in the AcoustoSizer.

A schematic diagram of the cell is shown in Fig. 6. The dispersion is located in the region between the pair of electrodes. The pulse from the gated amplifier is applied across these electrodes, generating the ESA sound waves. Voltage pulses rather than continuous sinusoids are applied to avoid interference by the sound wave emanating from the electrodes. The use of pulsed signals also avoids electrical heating of the suspension and the complications of multiple reflections of the waves at the electrodes and at the ends of the rods. The voltage pulse produced by the sound wave in the transducer on the right passes into the signal-processing electronics, which measures the amplitude and phase of the sinusoidal component of the pulse. These data are passed to the computer where it is stored for subsequent processing.

Since the ESA signal depends on particle motion and also on the acoustic property of the dispersion, the determination of particle motion from the ESA signal requires knowledge of the acoustic impedance of the dispersion. This parameter is measured using sensors associated with the rod on the left immediately after each ESA measurement. The signals from these

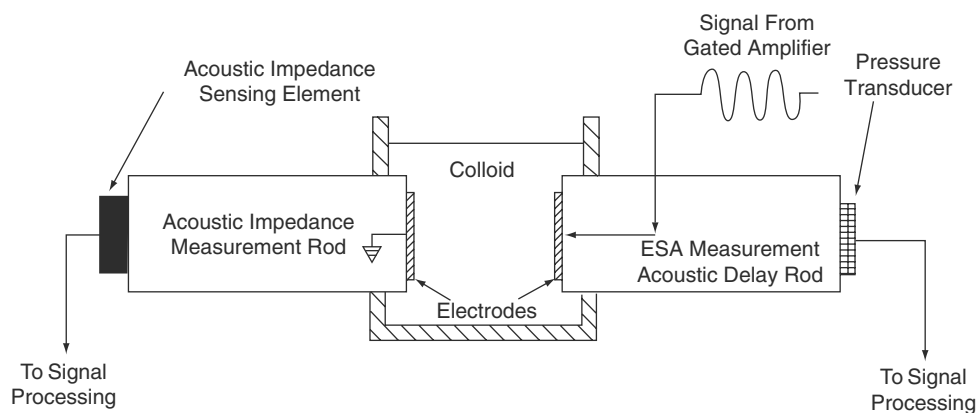

Fig. 6 A schematic diagram of AcoustoSizer measurement cell.

two rods are stored in the computer and are subsequently converted to a particle-velocity spectrum, and from that the zeta potential and size information is determined. The AcoustoPhor 8000 (PenKem, Inc.) is another example of a commercial system which determines zeta potential and the particle size of dispersions using these electro-acoustic effects.

APPLICATIONS

The practical significance of zeta-potential measurement lies in the fact that strong empirical correlation exists between the measured zeta potential of the system and the properties of the system which are the manifestation of the electrostatic interfacial phenomenon. Since the measurement of zeta potential can be conveniently performed, it becomes an ideal parameter for use in routine testing. Zeta-potential control has been successfully applied to various technical fields involving colloidal and non-colloidal systems.

Colloid Stability^[3,8,9]

The physical stability of a colloidal system is determined by the balance between the repulsive and attractive forces which is described quantitatively by the Deryaguin–Landau–Verwey–Overbeek (DLVO) theory. The electrostatic repulsive force is dependent on the degree of double-layer overlap and the attractive force is provided by the van der Waals interaction; the magnitude of both are a function of the separation between the particles. It has long been realized that the zeta potential is a good indicator of the magnitude of the repulsive interaction between colloidal particles. Measurement of zeta potential has therefore been commonly used to assess the stability of colloidal systems.

Electrostatic repulsive energy, V_R , at a given inter-particle distance is the work which must be performed to bring the particles to a specific point. Using the Debye–Huckel low-potential approximation and assuming equal spheres, V_R can be described by

$$V_R = 2\pi\epsilon a\psi_d^2 \ln(1 + \exp[-\kappa H]) \quad (4)$$

where a is the particle radius, H is the distance of separation between the two particles, and κ is the Debye parameter. The magnitude of V_R decreases in an approximately exponential fashion with increasing H and that its range decreases by increasing κ (i.e., by increasing electrolyte concentration and/or counterion charge number). V_R can be also influenced by other specific factors. Counter-ion adsorption in the Stern layer may cause a reversal of charge, so that V_R will be zero at the reversal-of-charge concentration and will

be positive (repulsion) at both below and above this concentration.

The attractive-force component between particles in a colloidal system is developed by summation of the London dispersion forces between all atom pairs in the particles. Neglecting retardation effects, the expression for the attractive energy V_A between two particles of radius a at a distance of separation H_0 , for $a \gg H_0$, is

$$V_A = A, a^{12}H_0 \quad (5)$$

where A is the effective Hamaker constant describing the attraction between the particles and the dispersion medium. It is apparent that V_A decreases as an inverse power of the distance between the particles.

According to DLVO theory, the total energy of interaction between colloidal particles is given by the sum of the attraction (V_A) and repulsion (V_R) energies:

$$V_T = V_R + V_A \quad (6)$$

Fig. 7A shows the total interaction energy curve for a colloidal system. At very close distances between the particles, the Born repulsion between adjoining electron clouds predominates, and the net interaction is repulsion. However, at slightly greater distances, the van der Waals attraction predominates over the electrostatic repulsion, and the net interaction is strong attraction as shown by the deep potential energy minimum V_P . At even greater distances, the net interaction is moderate attraction (a shallow secondary minimum V_S) because with increasing distance between two particles, electrostatic repulsion weakens more rapidly than the van der Waals attraction energy. At intermediate distances, the electrostatic repulsion predominates and the net interaction becomes repulsion, with an energy barrier, V_m .

The attraction energy arising from van der Waals forces does not vary significantly with changes in the surface potential and electric double-layer properties of the colloidal particles. By contrast, changes in these two parameters have significant impact on the repulsion energy component of the total interaction energy. Therefore, at greater distances, a further increase in electrostatic repulsion will result in a total repulsive net interaction curve without the secondary minimum (Fig. 7B). However, as the repulsive component of the interaction energy diminishes (i.e., the electrolyte concentration increases), the interaction curve becomes totally attractive and rapid coagulation (controlled by particle-diffusion rate) of the colloidal particles takes place (Fig. 7C).

An empirical relationship was developed between the zeta potential and the coagulation behavior of a variety of systems. Deryaguin shows that a rapid

Fig. 7 Variation of the attraction and repulsion energies and the total energy of interaction between two colloidal particles with interparticle distance.

decrease in stability can be expected when the following conditions are met.^[3]

$$4\pi\epsilon\zeta^2/\kappa A \quad (7)$$

For a given system, A and ϵ are fixed; therefore, varying the electrolyte (in type and concentration) should produce instability at a particular value of ζ^2/κ . The validity of using zeta potential in describing the coagulation process should come as no surprise because it characterizes the potential of the diffuse part of the electric double layer which is involved in double-layer overlap and which plays an important role in the coagulation process. When the zeta potential is sufficiently high to produce a potential barrier opposing coagulation, the rate of coagulation is slowed by a factor W , called the stability ratio, defined as the ratio of the total number of particle collisions to the number of collisions forming permanent doublets. Wiese and Healy reported an excellent correlation between the theoretical values for W (calculated from the zeta potential) and the experimental values for TiO_2 and Al_2O_3 sols as a function of pH (Fig. 8) and electrolyte (KNO_3) concentration.^[10] Rapid coagulation, whether induced by pH or KNO_3 concentration changes, occurs at a value of $|\zeta| \leq 14 \pm 4 \text{ mV}$, corresponding to $\zeta^2/\kappa = 6 \times 10^{-4} (\text{mV})^2 \text{ cm}$.

Pharmaceutical Systems

Most of the pharmaceutical dispersions can be classified as colloidal systems, although this depends upon

the size of their dispersed phase. Therefore, in general, the theoretical and empirical relationships between zeta potential and colloid stability are applicable to the physical stability of these pharmaceutical systems. However, the practical aspects of applying zeta potential to these systems may vary because of differences in the chemical composition and physical state of their dispersed and continuous phases. In addition, the practical significance of zeta-potential measurement may be different for products which differ in their clinical requirements such as route of administration and consequent in vivo disposition.

Emulsions

Emulsions have been widely used as vehicles for oral, topical, and parenteral delivery of medications. Although the product attributes of an emulsion dosage form are dependent on the route of administration, a common concern is the physical stability of the system, in particular the coalescence of its dispersed phase and the consequent alteration in its particle-size distribution and phase separation. The stabilization mechanism(s) for an emulsion is mainly dependent on the chemical composition of the surfactant used. Electrostatic stabilization as described by DLVO theory plays an important role in emulsions (O/W) containing ionic surfactants.^[11] For O/W emulsions with low electrolyte content in the aqueous phase, a zeta potential of 30 mV is found to be sufficient to establish an energy maximum (energy barrier) to ensure emulsion stability.^[11] For emulsions containing

Fig. 8 Comparison of theoretical and experimental stability ratios for TiO_2 (0.05 g/L) and Al_2O_3 (0.15 g/L) colloids in 10^{-4} M KNO_3 .

non-ionic surfactants (polymers), the principal stabilization mechanism is the repulsion between the adsorbed polymer chains on the surface of the oil globules called steric stabilization.^[11] In such a case, zeta-potential measurement may have limited values with respect to emulsion stability.

In the past, injectable emulsions were administered intravenously to provide patients with vegetable oils as a major energy source in nutrition therapy.^[12] In recent years, injectable emulsions have been found to be very effective vehicles for the parenteral delivery of water-insoluble drugs.^[13] Because of toxicological considerations, surfactants which are used in the formulation of injectable emulsions have been largely limited to mixtures of phospholipids which are either derived from egg (egg yolk lecithin) or soybean (soybean lecithin). The majority of the phospholipids (80–90%) are phosphatidylcholine (PC) and phosphatidylethanolamine (PE), which are uncharged at physiological pH. But the presence of small quantities (2–5%) of acidic components, largely phosphatidylserin (PS) and phosphatidylglycerol (PG), which are ionized at pH 7, confers a surface charge of approximately –40 to –50 mV on the emulsion particles.^[14] Therefore, the stability of these emulsions is mainly attributable to electrostatic stabilization. Any factors which alter

the surface potential are likely to have an impact on overall emulsion stability. The physical instability of an injectable emulsion as manifested by an increase in particle size ($>5\mu\text{m}$) will result in serious clinical consequences such as formation of pulmonary emboli.^[15] Therefore, the extent of electrostatic stabilization of an injectable emulsion as measured by its zeta potential has been an important parameter in the characterizing and monitoring of its physical stability.

A relative wealth of information relating to the application of zeta potential to injectable emulsions has been documented with respect to the use of total nutrient admixtures (TNA).^[16] Total nutrient admixtures are prepared by mixing the lipid emulsion with other components (i.e., dextrose, amino acids, and electrolytes) in a single container prior to administration. Depending on composition, the mixtures vary widely in their stability and may show clinically unacceptable coalescence after different periods of storage time.

When the electrostatic stabilization of the emulsion is considered, the electrolytes (monovalent and divalent) added to the mixture are the major destabilizing species. The zeta potential of the emulsion particles is a function of the concentration and type of electrolytes present. Two types of emulsion particle-electrolyte (ions) interaction are proposed: non-specific and specific adsorption.^[16] In non-specific adsorption the ions are bound to the emulsion particle only by electrical double-layer interactions with the charged surface. As the electrolyte concentration is increased, the zeta potential asymptotes to zero. As the electrostatic repulsion decreases, a point can be found where the attractive van der Waals force is equal to the repulsive electrostatic force and flocculation of the emulsion occurs (Fig. 9A). This point is called the critical flocculation concentration (CFC).

DLVO theory predicts that the CFC should vary inversely with the sixth power of the ion charge. The application of CFC alone fails to correlate the TNA stability with electrolytes in the mixtures. This is because divalent ions (calcium and magnesium) adsorbed specifically on the emulsion particles through their complexation with the negatively charged acidic phospholipids. Fig. 9B demonstrates the relationship between the concentration of a specifically adsorbed ion and the zeta potential and flocculation rate of an injectable emulsion. The increase in electrolyte concentration causes the particle charge to pass through zero; this is referred to as the point of zero charge (PZC). At this point the flocculation rate is at maximum; a further increase in electrolyte concentration causes a surface-charge reversal of the particles and increases in zeta potential (opposite sign) as well as a decrease of the flocculation rate from its maximum value.

The effect of pH on the stability of an injectable emulsion was also followed by measuring its zeta

Fig. 9 Zeta potential and flocculation rate of a parenteral emulsion in the presence of a non-specifically adsorbing electrolyte (A) and a specifically adsorbing electrolyte (B).

potential (Fig. 10). At pH 7 the ionization of PS and PG imparts a surface negative charge (-30 to -50 mV) to the emulsion particles. As the pH is reduced, this ionization is suppressed until the charge is zero at a pH of 3.2. Further decreases in pH cause the protonation of the phospholipid and a positive surface charge (positive zeta potential). Significant progress has been made in relating the electrokinetic properties of phospholipid-stabilized emulsions to their instability when influenced by other TNA ingredients.^[17,18] Washington and his coworkers have attempted to develop a model to predict emulsion stability in TNAs

using DLVO-based methods in the measurement of the zeta potential of the system.^[19]

Suspensions

Pharmaceutical suspensions are dispersions of solid particles in a suspending medium or vehicle (usually aqueous in nature). When the suspended solids are less than $1\ \mu\text{m}$, the system is referred to as a colloidal suspension. When the particle sizes are greater than about $1\ \mu\text{m}$, the system is called a coarse suspension. The practical upper limit for particles in a coarse suspension is approximately $50\text{--}75\ \mu\text{m}$. Depending on the affinity or interaction between the dispersed phase and the dispersion medium, a colloidal dispersion can be classified as lyophilic (hydrophilic) or lyophobic (hydrophobic).^[20]

The dispersion of hydrophilic particulate solids in water occurs spontaneously and gives rise to a thermodynamically stable system such as colloidal silicone dioxide or microcrystalline cellulose. Hydrophobic solids are not easily wetted and are not dispersed spontaneously in water as sulfur, clays, and most non-polar organic compounds. The van der Waals attractive forces between particles cause them to aggregate, since the solvation forces which promote dispersal in water are weak. Therefore, aqueous dispersions of hydrophobic solids can only be stabilized kinetically to resist flocculation and coagulation, which can be defined by referring to the total interaction energy curve (Fig. 7). Flocculation indicates the association of particles in the secondary minimum and coagulation is the aggregation of particles in the primary minimum. Since the attractive forces between particles in a

Fig. 10 Zeta potential of a parenteral emulsion as a function of pH.

flocculated system are relatively weak, they can be redispersed and the process is reversible. In contrast, coagulation is irreversible as attractive forces operating between particles in the primary minimum are difficult to overcome.

When electrostatic repulsion is predominant between particles in a suspension, it is called a deflocculated system. For particles with a diameter of 2–5 μm , Brownian movement counteracts sedimentation to a measurable extent at room temperature by keeping the dispersed particles in random motion. This results in a system which is physically stable with respect to sedimentation and flocculation.^[20] However, in a deflocculated suspension consisting of larger particles (coarse), gravitational force counteracts Brownian movement and sedimentation occurs.^[21] At the bottom of the container, a compact sediment with strong attractive forces between the particles is formed and it cannot be easily redispersed. This phenomenon is referred to as caking. The prevention of caking has been one of the main objectives in preparing stable coarse suspensions.^[21,22] Although flocculation is referred to as a physical instability of colloids, flocculated suspensions are pharmaceutically acceptable since they are non-caking. In a flocculated suspension, particles attract each other (at the secondary minimum) loosely to form flocs which tend to settle together, creating a distinct boundary between the sediment and the supernatant. Particles in flocs are thereby easily redispersed after settling.

Controlled flocculation is a process by which flocculation of particles in a suspension is purposely produced by adding flocculating agents. One of the most effective methods of achieving controlled flocculation is to reduce the electrostatic repulsive forces between particles.^[21,22] Electrolytes have been shown to be effective flocculating agents. Zeta-potential measurement has been a valuable tool in monitoring and evaluating the influence of various electrolytes on the flocculation phenomena in coarse suspensions.^[23] Sedimentation volume F , which is the ratio of the volume of sediment to the original volume of the suspension, is a useful parameter in measuring the extent of flocculation of the suspension. An excellent correlation between the zeta potential, sedimentation volume, and caking was found for a series of bismuth subnitrate suspensions containing various concentrations of potassium phosphate monobasic (Fig. 11).^[24] The addition of potassium phosphate monobasic causes a decrease in the zeta potential of the suspension because of partial neutralization of the positive surface charge on the bismuth subnitrate particles. With the decrease in the zeta potential (positive), the suspension becomes flocculated and non-caking, accompanied by an increase in the sedimentation volume. The continued addition of electrolyte causes the zeta potential to fall to zero and

Fig. 11 A caking diagram showing the flocculation of a bismuth subnitrate suspension by means of the flocculating agent, potassium monobasic phosphate.

then increases in a negative direction. The suspension remains flocculated until the zeta potential becomes sufficiently negative to effect deflocculation of the system, which is shown by a decrease in the sedimentation volume and an increase in caking tendency.

Zeta potential has also found an application in relating the surface-charge characteristics of a suspension to properties other than physical stability. Heyd and Dhabhar improved the fluidity of concentrated antacid suspensions by adding a colloidal polyelectrolyte (carrageenan sodium) which is called a fluidizing agent.^[25] As the concentration of the fluidizing agent increases, the zeta potential of the suspension changes from positive to negative, accompanied by a reduction in viscosity of the suspension. The mechanism for this viscosity-thinning phenomenon is believed to be the selective adsorption of the negatively charged fluidizing agent onto the positively charged antacid particles. This imparts an electronegative charge (as measured by the zeta potential) onto the antacid particles, decreasing the demand for water.

In the literature, the reported use of zeta potential measurement for non-aqueous suspensions is relatively infrequent because non-aqueous suspensions only represent a small percentage of all medicated suspensions. Su and others evaluated the flocculation–deflocculation behavior of cefazolin sodium in non-aqueous media and the effect of surfactants as measured by zeta potential along with sedimentation and porosity measurements.^[26] A significant difference in zeta potential was observed when the particles were dispersed in peanut oil and ethyl oleate. The addition of lecithin reduced the zeta potential of cefazolin sodium, resulting in a deflocculated state accompanied by a decrease in sedimentation volume. The effect of surfactant

excipient on the zeta potential of salbutamol in trichlorofluoroethane (P113) for metered-dose inhalation was determined.^[27] Although the zeta potential of the particles is decreased (more negative) by the addition of oleic acid, the overall zeta potential is too low to be effective in providing the system with adequate electrostatic stabilization, particularly in media with a low dielectric constant (organic solvents).

Microparticulate drug-delivery systems, including microspheres and nanoparticles, are suspensions when they are administered in a liquid medium. Microspheres are solid particles containing dispersed drug in either solution or microcrystalline form and range in size from 1 to 1000 μm . Although most microspheres are outside the conventional colloidal size range, in pharmaceutical literature microspheres with sizes up to approximately 15 μm are still considered as colloidal delivery systems. Nanoparticles are similar to microspheres but have particle sizes in the range of 0.01–1 μm ; therefore, they form colloidal suspensions when dispersed in a liquid medium.^[28] Zeta-potential measurement is an important surface-characterization technique which provides information regarding the surface charge of these microparticulate systems. The effect of surface charge (zeta potential) on the physical stability of these systems (i.e., aggregation) can be predicted using the DLVO theory, although steric stabilization plays an important role in systems with surface-adsorbed macromolecules.

When the microparticles are administered intravenously, surface charge is an important parameter affecting the interaction between the microparticles and other biological components of the body and their subsequent *in vivo* distribution and disposition.^[29] Tabata and Ikada reported that phagocytosis of polymer microspheres by macrophages is enhanced as the absolute value of zeta potential increases for both the negatively charged and the positively charged surfaces, while the lowest phagocytosis is shown for the surface with a zeta potential of zero.^[30] The uptake of charged serum components by nanoparticles (opsonization) in blood is considered to be the first step leading to phagocytosis by liver and spleen macrophages. Muller and his coworkers determined the increase in zeta potential of non-particles in serum as a measure of the extent of opsonization and used this as selection criteria for *i.v.* drug carriers avoiding liver/spleen uptake.^[31]

Liposomes

Liposomes are phospholipid-based vesicles which have been studied as delivery systems to target drugs to specific sites in the body.^[32–34] The surface of a liposome can be neutral or negatively or positively charged, depending on the composition of lipids used. For

charged liposomes, their surface potential is a critical factor affecting their physical stability and *in vivo* performance. Instead of their surface potential, zeta-potential measurement is frequently used in the investigation of the behavior of liposomes as influenced by their surface charge. Liposomes in aqueous dispersions have a tendency to aggregate and subsequently fuse on storage. This physical instability potentially limits their application as dosage forms.

Crommelin incorporated charge-inducing components in liposome bilayers to produce electrostatic repulsion between liposomes, thus increasing the shelf life of the dispersion.^[35] He investigated the effect of including stearylamine or phosphatidylserin on the zeta potential of phosphatidylcholine-cholesterol-containing liposomes. A correlation between the aggregation stability of negatively charged liposomes and the increments in the surface-charge density at both low and high ionic strength was established, whereas the positive liposome dispersions were found to be unstable.

Carrion and his coworkers investigated the effect of incorporating phosphatidic acid on the zeta potential and aggregation of large unilamellar vesicle liposomes of phosphatidylcholine in the presence of neutral electrolytes.^[36] Their results show that increasing concentrations of phosphatidic acid in lipid bilayers resulted in high zeta potential and enhanced physical stability of the liposomes. The destabilizing effect of divalent cations (i.e., calcium ions) on charged liposomes has been well documented and is attributable to the reduced surface potential of the liposomes as the result of cation binding.^[37–39]

The effect of calcium ions on the aggregation behaviors of neutral liposomes composed of egg phosphatidylcholine and dipalmitoylphosphatidylcholine was investigated by Mosharraf and coworkers.^[40] Both systems displayed a high negative zeta potential in deionized water, probably the result of adsorption of hydroxyl ions. A reasonable correlation was found in both cases between particle-size increase and zeta potential decrease of the system, suggesting that the mechanism by which the aggregation takes place is related to the surface-charge characteristics. Although it has long been established that liposomes composed of neutral phospholipids acquire negative surface charge via anion adsorption, Makino and his group in Japan found that neutral liposomes exhibit negative zeta potential in buffer solution containing no chloride ion.^[41] They also reported that changes in the ionic strength and temperature causes the zeta potential of neutral liposomes to reverse sign. They proposed that the reversal of zeta potential is triggered by changes in the direction of the dipole connecting the negative charge of the phosphatidyl group and the positive charge of the choline group consisting the head group of a lipid molecule.

The study of the effect of drug-loading on the zeta potential of liposomes provides information regarding the drug-liposome interaction. Lawrence and others reported that the loading of polymyxin B, a polycationic antibiotic in negatively charged liposomes, results in the decrease of zeta potential, indicating electrostatic attraction between the positive drug and the negative lipid bilayer.^[42] That the highest drug-loading is found in negatively charged liposomes in comparison to positively charged and neutral liposomes further supports this electrostatic drug-liposome interaction. Beschiaschvili and Seelig investigated the binding of a cyclic somatostatin analogue, a positively charged peptide, to negatively charged multilamellar liposomes.^[43] From the binding isotherm and the zeta-potential measurement, they were able to describe a partition equilibrium between the peptide and the negatively charged membrane with a surface-partition constant. They concluded that most of the peptide molecules are embedded in the headgroup region with little penetration into the lipid core.

The measurement of the zeta potential of liposomes provides valuable information relating to their in vivo performance because, in addition to size, the surface charge of liposomes is an important determinant of their clearance from the general circulation and their tissue disposition after parenteral administration. Large multilamellar liposomes are cleared from the circulation much more rapidly than small unilamellar liposomes. Among small unilamellar liposomes, however, those with a negative surface charge are cleared rapidly, but positively charged or uncharged liposomes remain in the circulation for longer periods.^[44] Rahman and his coworkers compared the pharmacological and therapeutic effects of adriamycin entrapped in positively charged and negatively charged liposomes in rats.^[45] They found that less cardiotoxicity was associated with the drug entrapped in the positively charged liposomes which exhibited lower in vivo uptake by cardiac tissue. When liposomes are employed to target drugs to lymph nodes, their surface charge has been shown to affect their lymphatic uptake from subcutaneous and intraperitoneal injection sites.^[46] Patel showed that negatively charged liposomes yield the highest localization in the lymph nodes, followed by positively charged and neutral ones. The drainage of negatively charged liposomes has also shown to be faster than that of positive liposomes after intraperitoneal administration.^[47]

CONCLUSIONS

Zeta-potential measurement has long been recognized as an excellent tool for characterizing colloidal systems. Its practical significance stems from the fact that

it allows the quantitation of the electrostatic repulsion between particles, which is one of the most important forces governing the behavior and physical stability of colloidal systems. In recent years, the concept of zeta potential has been applied to areas beyond classical colloidal sciences and industrial processes. Pharmaceutical sciences are the new fields to which the application of zeta potential has been extended. The expanding role of zeta potential in these fields is attributable to the advance in modern instrumentation of zeta potential measurement, the rapid development of colloidal drug-delivery systems, and the emphasis on interdisciplinary basic research. While good correlation has been demonstrated for zeta potential and in vitro properties of colloidal drug-carrier systems, the understanding of the impact of zeta potential in organ distribution and in vivo clearance of these systems has been the focus of additional research efforts.

VOLUME 1

Encyclopedia of PHARMACEUTICAL TECHNOLOGY Third Edition

about the second edition...

"...The depth and breadth of coverage...make it an excellent source for academic and special libraries supporting research programs in the health sciences, pharmacology, and chemical engineering."

—*American Reference Books Annual*

"...the value of the encyclopedia is in its tremendous breadth....highly recommended...should be in the library of any company or institution involved in pharmaceuticals."

—*Organic Process Research and Development*

about the third edition...

Presenting authoritative and engaging articles on all aspects of drug development, dosage, manufacturing, and regulation, this **Third Edition** enables the pharmaceutical specialist and novice alike to keep abreast of developments in this rapidly evolving and highly competitive field. A dependable reference tool and constant companion for years to come, the **Third Edition** will offer completely new entries that cover critical issues in the field such as the impact of genomics, biotechnology, and implants on drug discovery, targeting, delivery, and formulation. In addition, it will address new regulatory issues, such as the changes in advertising regulations, and emerging FDA procedures.

Bringing together acknowledged leaders from every specialty related to pharmaceutical technology, this **Third Edition** stands as an indispensable and single-source reference at the forefront of pharmaceutical technology and research...keeps pharmaceutical professionals and researchers at the cutting-edge of their disciplines with more than **70 NEW** entries on topics of utmost importance in the field including advances in systems validation, processing techniques, patent issues, noninvasive drug delivery, and the commercialization of drugs and dosage forms...provides a comprehensive overview of most specialty and subspecialty topics relating to the research, manufacture, marketing, and use of pharmaceuticals...offers a reader-friendly and timely collection of references to the pharmaceutical market...and contains an abundance of articles on pharmaceuticals, pharmacokinetics, analytical chemistry, quality assurance, drug safety, and manufacturing processes.

about the editor...

JAMES SWARBRICK is President of PharmaceuTech, Inc., Pinehurst, North Carolina. He has served in a number of industrial and academic positions, including Director of Product Development at Sterling-Winthrop Research Institute, Rensselaer, New York and Vice President for Research and Development and Vice President for Scientific Affairs at AAI Pharma, Wilmington, North Carolina. Prior to joining AAI Pharma, he was Professor and Chairman of the Division of Pharmaceutics at the University of North Carolina at Chapel Hill School of Pharmacy. He has also held academic positions at London University, Sydney University in Australia, and the University of Connecticut. He is a Fellow of the American Association of Pharmaceutical Scientists, the Academy of Pharmaceutical Sciences, the Royal Society of Chemistry, and the Royal Pharmaceutical Society of Great Britain. He has also served as a member and chairman of the FDA's Generic Drugs Advisory Committee, and currently serves as Chairman of the PhRMA Foundation's Pharmaceutics Advisory Committee, as well as a member of PhRMA Foundation's Scientific Advisory Committee. Dr. Swarbrick received the B.Pharm. degree (1960) from London University, England, the Ph.C. diploma (1961) from the Royal Pharmaceutical Society of Great Britain, and the Ph.D. degree (1964) in pharmaceutics and the D.Sc. degree (1972) in surface and physical chemistry from London University, England.
